

DRAINAGE DESIGN MANUAL

***for Maricopa County,
Arizona***

Volume II

HYDRAULICS

January 28, 1996

*Flood Control District
of Maricopa County
2801 West Durango Street
Phoenix, Arizona 85009
(602) 506-1501*

Acknowledgments

This manual was originally prepared by NBS Lowry Engineers and Planners, and McLaughlin Water Engineers, Ltd. under the direction of the Flood Control District. Work groups composed of representatives from the Flood Control District and various communities in Maricopa County were formed to advise the consultants about the applicability of technical criteria, special problem areas, and resolve conflicts over potential differences in drainage standards between communities. The Flood Control District would like to thank the following committee members for all their help in the development of the original manual:

Ray Acuna	Bob Draper	Paul Kienow	Greg Rodzenko
Tom Ankeny	Bill Erickson	Lionel Lewis	Joe Rumann
Francisco Badilla	Cora Fernandez	Sal Misseri	Shane Shovestull
Ellery Biathrow	Brian Fry	Tim Murphy	Don Snyder
Jim Bond	Greg Grendell	Roger Olsen	Thomas Sonnemann
Bill Boring	David Gulino	Lorenzo Ortiz	Doug Sovern
Pedro Calza	Long-Cheng Huang	Richard Perry	Felicia Terry
Christopher Clawson	Dennis Hustead	Doug Plasencia	Joe Tram
Chuck Connett	Dave Johnson	John Pflaum	Steven Tucker
Greg Crossman	Nick Karan	Ed Raleigh	Cyrous Vahidnia
Ron Degroot	Besian Khatiblou	David Ramirez	Cindy White
Teresa Dominguez	Davar Khalili	Valerie Rice	

The manual developed by NBS Lowry and McLaughlin Water Engineers was released in a draft format (November 1991) for review and comment by public and private sector engineers, and other interested parties. District staff revised the manual using comments received from the public and reissued the manual with a date of September 1992.

This edition of the manual was revised by District staff based on comments received from users of it. Letters were sent to all the Cities and Towns in Maricopa County informing them of the revisions to the manual, and inviting them to review the manual before the District released it. The District would like to thank those communities who responded with comments and the members of the engineering community who voluntarily reviewed portions of this edition.

Comments

Users of this manual are strongly encouraged to submit any comments, criticisms, or findings of errors. This information should be addressed to:

Engineering Division Manager
Flood Control District of Maricopa County
2801 West Durango
Phoenix, AZ 85009

Future editions of this manual will include a greater use of the Metric system of measurement. Because of ongoing legal and technical changes in the field of stormwater management, revisions to this manual will be required from time to time. With the exception of correcting typographical errors, such revisions will probably take place every three to five years.

Revisions

The following is a summary list of the changes to the September 1, 1992 edition of the *Drainage Design Manual, Volume II, Hydraulics*. This summary of the revisions is only presented as an aid for users of the previous edition, it doesn't document every revision to the manual. Typically corrections for spelling, typographical errors, and revisions for readability are not documented here. When sections were moved, the renumbering of subsequent sections wasn't usually identified here. Due to the use of a new word processing program, there can be significant differences in the page numbering between this edition and previous editions. The sections or page numbers used in this list refer to the September 1, 1992 manual, unless otherwise stated.

1. *Comments*: Added this page requesting comments on the manual.
2. *Acknowledgments*: Added this page that identifies and thanks those individuals who have contributed to the manual in some official format.
3. *Revisions*: Added this section to summarize some of the significant changes to the September 1, 1992 edition.
4. *Chapter 1*: Changed the use of the phrase "regulation" to "recommended uniform policy requirement." Revised the descriptions of the chapters to reflect the revisions made to the chapters. Revised the wording of the recommended uniform policy requirements to match with what is in the chapters.
5. *Chapter 2*: In Table 2.1 changed the V_{min} from 2.5 to 3.0 fps for the 50 year peak frequency on cross road culvert collector and arterial streets. Revised the wording for the finish floor elevation for buildings within a FEMA floodplain area. In the footnote changed the minimum discharge for delineating a floodplain for submittal to FEMA from 1,000 cfs to 500 cfs. Also, added Section 2.4 (References).
6. *Chapter 3*: In Section 3.1 made minor corrections to some of the definitions. In Table 3.1 revised the second footnote. Renumbered the equations to account for identifying a new equation 3.2 (January 28, 1996). For equation 3.2 (January 28, 1996) added a sentence on what terms were inserted into equation 3.1 in order to derive equation 3.2 (January 28, 1996). Revised the wording in the recommended uniform policy box on page 3-6.
7. *Chapter 4*: This chapter was divided into two chapters. The new Chapter 4 (January 28, 1996) is titled Storm Drains, and the new Chapter 5 (January 28, 1996) is titled Culverts and Bridges. In Section 4.1 deleted and added definitions as needed for the revisions to the new chapter. Replaced the whole method for analyzing storm drains (Section 4.2). This required the addition of several new sections and the complete revision to several old sections. Revised the wording slightly in the recommended uniform policy requirement on page 4-5. Added a section on minimum slope as Section 4.2.2.3 (January 28, 1996). Had to revise the numbering for some of the sections because of the new Section 4.2.2.3. In Section 4.2.2.5 added a paragraph on minimum pipe size. Changed the title of Section 4.2.2.6 and revised some of the wording slightly. The methods to calculate the various losses are now all located in Section 4.3.3 (January 28, 1996).

The new Chapter 5 (January 28, 1996) on Culverts and Bridges begins with Section 4.3 from the September 1, 1992 edition. Because of being broken out into a new chapter all the numbering for the sections changed. The wording in the recommended uniform policy requirement boxes on pages 4-73, 4-74, 4-81, 4-82, 4-83, and 4-85 were changed. In Section 4.3.2.2 revised the minimum velocity to 3 ft/s. In Section 4.3.2.7 the italic subsections were made into numbered sections. Sections 4.3.3.6 and 4.3.3.3 were relocated under Section 5.2.2 (January 28, 1996). This was done in order to locate all the various losses together in one section.

8. *Chapter 5:* The chapter had to be renumbered to 6 (January 28, 1996). Section 5.2 was made into the first section of the chapter, which is consistent with the other chapters. Revised the recommended uniform policy requirement boxes on pages 5-12, 5-16, 5-30, 5-33, and 5-41. In Figure 5.1 changed the side slope of the riprap channel to 3:1. In Section 5.5.1.2 deleted the paragraph on the slope paving method and Figure 5.7. In Section 5.5.2.2 thickness of the lining is now determined using an ADOT reference. Table 5.4 was revised. On page 5-38 revised the thickness required for the riprap layer. In Section 5.5.3.3 revised the method for sizing riprap. Deleted Table 5.7. Revised Figure 5.10 to agree with the text. Changed the title of Table 5.10. In Section 5.6.3.1 changed the Q_{100} in the example problem to 565 cfs.
9. *Chapter 6:* The chapter was renumbered to 7 (January 28, 1996). Section 6.2 was made into the first section of the chapter, which is consistent with the other chapters. Revised the definitions of some of the symbols. Made the fourth paragraph on page 6-14 into a recommended uniform policy requirement. Moved the hydraulic jump analysis (Section 6.8.1) to just after Section 6.3.2.3 (September 1, 1992).
10. *Chapter 7:* Made this part of the new Chapter 5 (January 28, 1996) on Culverts and Bridges. Deleted Sections 7.3.1.1 to 7.3.1.4 because there wasn't enough information presented here to do a complete analysis of a bridge, and most designers will use a computer program for the analysis. From these sections only the recommended uniform policy requirement on page 7-7 needed to be kept. Revised the wording of the recommended uniform policy requirements on page 7-11. The minimum freeboard for a bridge was revised to two feet for the 100-year event. Section 7.3.2.1 was revised.
11. *Chapter 8:* Created a new Section 8.1, which defines the symbols used in this chapter and modified the numbering of the other sections because of it. In Section 8.2.1.2 added an equation for determining the volume of retention required. Also, added a new recommended uniform policy requirement dealing with off-site flows. Revised the wording for the recommended uniform policy requirements on pages 8-4, 8-6, 8-7, and 8-18. Added a new section dealing with sedimentation right before Section 8.2.1.3. In Section 8.2.1.8 added a recommended uniform policy requirement about dry wells. The recommended uniform policy requirements on pages 8-18, 8-24, 8-25, and 8-30 were dropped although the text remains.
12. *Chapter 9:* Revisions to this chapter were only to correct typographical errors.
13. *Glossary:* Revisions to this chapter were only to correct typographical errors
14. *Index:* A subject index was added to make it easier to find information in the manual.

Table of Contents

1	Introduction	1-1
1.1	Purpose	1-1
1.2	Background	1-1
1.3	Scope	1-2
1.3.1	Introduction	1-2
1.3.2	Hydrology	1-2
1.3.3	Street Drainage	1-2
1.3.4	Storm Drains	1-3
1.3.5	Culverts and Bridges	1-3
1.3.6	Open Channels	1-3
1.3.7	Hydraulic Structures	1-4
1.3.8	Detention and Retention	1-4
1.3.9	Pump Stations	1-4
1.4	Recommended Uniform Policy Requirements	1-5
2	Hydrology	2-1
2.1	Methodology	2-1
2.2	Criteria	2-2
2.3	Master Drainage Planning	2-2
2.4	References	2-4
3	Street Drainage	3-1
3.1	Definition of Symbols	3-1
3.2	Streets	3-2
3.2.1	Design Criteria for Streets and Gutters	3-2
3.2.1.1	Design Frequency	3-2
3.2.1.2	Pavement Encroachment	3-3
3.2.1.3	Theoretical Capacity	3-6
3.2.1.4	Reduction Factors	3-6
3.2.1.5	Transition at Curb and Gutter End	3-9
3.2.2	Design Criteria for Intersections	3-9
3.2.2.1	Theoretical Capacity	3-9
3.2.2.2	Allowable Capacity	3-11
3.2.3	Design Criteria for Roadside Ditches	3-11
3.2.3.1	Permissible Use	3-12
3.2.3.2	Street Capacity for the Design Storm	3-12

	3.2.3.3	Geometry	3-12
	3.2.3.4	Rural Crown Ditch	3-12
3.3		Catch Basin	3-13
	3.3.1	Catch Basin Types	3-13
	3.3.1.1	Curb Opening Catch Basins	3-13
	3.3.1.2	Grated Catch Basin	3-15
	3.3.1.3	Combination Catch Basin	3-15
	3.3.1.4	Slotted Drain Catch Basins	3-15
	3.3.2	Catch Basin Applications	3-15
	3.3.2.1	Sump Conditions	3-15
	3.3.2.2	Continuous Grade Conditions	3-16
	3.3.2.3	Shallow Sheet Flow Condition	3-16
	3.3.2.4	Large Inlet Inflows	3-16
	3.3.3	Allowable Catch Basin Capacities	3-16
	3.3.4	Catch Basin Design Procedures	3-17
	3.3.4.1	Curb Opening Catch Basins	3-17
	3.3.4.2	Grated Catch Basins	3-20
	3.3.4.3	Combination Catch Basins	3-24
	3.3.4.4	Slotted Drain Catch Basins	3-24
	3.3.5	Design Aids	3-26
3.4		References	3-49
4		Storm Drains	4-1
4.1		Definition of Symbols	4-1
4.2		Storm Drains	4-2
	4.2.1	Interaction of Storm Drain Systems with other Systems	4-2
	4.2.2	Storm Drain Criteria	4-2
	4.2.2.1	Maximum Velocity	4-2
	4.2.2.2	Minimum Velocity	4-2
	4.2.2.3	Minimum Slope	4-3
	4.2.2.4	Hydraulic/Energy Grade Line	4-3
	4.2.2.5	Materials	4-4

Introduction

1.1 Purpose

The objective of the *Drainage Design Manual for Maricopa County, Volume II, Hydraulics*, is to provide criteria and design guidance for storm drainage facilities in Maricopa County. There are two reasons to develop such a manual: 1) it provides a convenient source of technical information that is specifically tailored to the unique hydrologic, environmental, and social character of Maricopa County; and 2) it provides a consistent set of criteria that, when used by the local governing agencies and the land development community, will result in uniform drainage practices throughout the county. Use of Volume II of the *Drainage Design Manual for Maricopa County* will result in improved hydraulic performance of drainage facilities, uniformity in design practices across jurisdictional boundaries, and reduction of conflict between the regulatory agencies and the land development community. Recommended uniform policy requirements have been highlighted by using a ruled box, for example:

This is how recommended uniform policy requirements will be highlighted in this manual.

1.2 Background

This manual was produced by a team of consultants under contract to the Flood Control District of Maricopa County. Beginning in 1987, the manual was developed through a highly interactive process involving work groups for each major topic. The work groups were composed of the engineering consultant, the Flood Control District, representatives of the various communities in Maricopa County, and representatives of home builders

and land developers. The work groups were charged with advising the consultant about applicability of technical criteria, special problem areas to be addressed, and resolving conflict over potential differences in drainage standards between communities.

1.3 Scope

The *Drainage Design Manual for Maricopa County, Volume II, Hydraulics*, is divided into nine chapters that address the major subject areas of hydraulic design. The intent of this manual is to provide general design guidance for designs that are common to the Maricopa County environment. Complex designs requiring specific expertise are not included in this manual; however, where design exceeds the scope of this manual, the user is referred to documentation appropriate for that design. The following sections briefly summarize each of the chapters in the manual.

1.3.1 Introduction

Chapter 1 defines the purpose, background, and scope of the manual along with a brief summary of each chapter. For the user's convenience and quick reference, all of the recommended uniform policy requirements are listed in Chapter 1 along with the page number where they are located in the manual.

1.3.2 Hydrology

Chapter 2 provides an overview of the hydrology criteria for drainage structures; the flood hydrology that is recommended for use in Maricopa County is contained in Volume I of the *Drainage Design Manual for Maricopa County*. That procedure provides for the use of the Rational Method for small, uniform watersheds, and for use of the U.S. Army Corps of Engineers' HEC-1 Flood Hydrology Program for larger watersheds with diverse surface conditions. The procedure provides design rainfall criteria that have been developed specifically for Maricopa County, rainfall loss methods that are based on the best practical technology that is available for estimating surface retention losses and infiltration rates, and unit hydrograph procedures that have been selected and developed for the various land-uses in Maricopa County.

1.3.3 Street Drainage

Chapter 3 provides design guidelines for the drainage of streets using curbs and storm drain inlets. An overall approach to stormwater management includes using the street

system to transport runoff to storm drain inlets, and for transporting runoff from storms that exceed the capacity of the storm drain system. Design criteria, design procedures, and design aids are provided for streets and gutters, intersections, and roadside ditches. Catch basins are discussed in regard to alternatives and suggested applications, capacities, and design procedures. The procedures used in this chapter were primarily adapted from the Federal Highway Administration Hydraulic Engineering Circular No.12 (HEC-12), *Drainage of Highway Pavements* (FHWA, 1984).

1.3.4 Storm Drains

Chapter 4 provides coverage of storm sewers. A comprehensive treatment of storm sewers is provided including use of design aids for catch basins, manholes, and various types of storm sewer junctions.

1.3.5 Culverts and Bridges

Chapter 5 provides coverage of the design information required for the design of culverts. This includes the necessary design aids, guidance for treatment of culvert inlets and outlets, and scour protection at the culvert outlet. Use of example problems helps to illustrate the procedures to be used for most practical applications. The charts and procedures for culvert design used in this chapter were taken from the Federal Highway Administration Hydraulic Design Series No. 5 (HDS-5), *Hydraulic Design of Highway Culverts* (FHWA, 1985). Some brief guidelines are presented to follow when using inverted siphons. The design of bridges requires special training and experience in regard to hydraulic analyses, design of flow training works, and estimates of pier and abutment scour. Therefore, only an overview of the hydraulic analyses for bridge openings is presented. There is also a general discussion on scour.

1.3.6 Open Channels

Chapter 6 is devoted to the analysis and treatment of both natural and artificial channels. The scope of this chapter covers the more commonly encountered open channel design applications by designers who do not possess special design skills in open channel hydraulics. Applications involving rivers and large washes or channels, which are considered as non-rigid, require special design skills, and the design of these channels should not be attempted with the design techniques contained in this chapter. The simplified design procedure presented provides an appropriate level of analysis for most design problems that will be encountered for artificial channels. The simplified design procedure assumes a rigid channel, and is valid for both subcritical and supercritical flows. Channel linings of concrete, soil cement, riprap, wire enclosed rock (gabion), and grass are discussed in the manual. The analysis of natural channels is discussed in broader terms than is the treatment of artificial channels. Although the basic theory is the same for both channel types, more complex flow conditions (nonuniform and

unsteady flow) and concepts of sediment transport often need to be incorporated in the analysis of natural channels.

1.3.7 Hydraulic Structures

The hydraulic structures that are described in Chapter 7 are used to control or alter the flow characteristics, such as velocity, depth, energy, and other hydraulic characteristics, and to affect a change in the configuration of an open-channel, such as channel slope. The purpose of such structures is to achieve a safer, more stable, and improved maintainability of conveyance systems. Channel drop structures are a major topic of this chapter and guidance is provided for the design of baffle chute drops, vertical hard basin drops, vertical riprap basin drops, sloping concrete drops, and low flow check structures. Information is provided for the dissipation of energy at conduit outlet structures with emphasis on riprap protection for outlets with moderate flow conditions and concrete structures for more severe conditions. Guidance is provided for the design of channel transitions, supercritical flow chutes, and bends in supercritical flow. The manual provides instruction in the theory and use of the hydraulic jump as a means of energy dissipation. The design of various, appropriate hydraulic jump energy dissipators is included.

1.3.8 Detention and Retention

Chapter 8 presents the engineering methodologies and details associated with the planning, analysis, and design of detention and retention facilities. Detention and retention basins are man-made storage facilities that are intended to mitigate the effects of urbanization on storm drainage. They serve to reduce peak discharges and can also reduce the volume of storm runoff downstream of the basin under certain conditions. Since detention and retention basins often require a considerable commitment of land resources by the community or land developer, particular emphasis is placed on planning basins that are amenities, and, where possible, incorporate multiple-use concepts. National storm water quality standards are being promulgated and criteria for use of detention and retention basins that will not jeopardize the quality of surface water and ground water resources are presented. Safety concerns of such facilities are detailed along with the means to enhance safety. The theory and procedure for performing routing of an inflow flood through such facilities is provided along with a detailed example of the calculations.

1.3.9 Pump Stations

The criteria for use of pump stations in Maricopa County are provided in Chapter 9, however, the intent is to provide only an overview of the conditions that should be considered in the design of stormwater pumping facilities. Stormwater pump stations are used where gravity discharge is infeasible, such as depressed highway intersections,

or for the controlled release of outflow, such as from a detention or retention facility. Reference to another readily available document for the rigorous design of stormwater pump stations is also provided.

1.4 Recommended Uniform Policy Requirements

The following table provides a brief overview of the recommended uniform policy requirements contained in this manual, along with the page numbers for your reference.

Recommended Uniform Policy Requirements	Page
A widely-accepted software program may be used in lieu of the design procedures in this manual. However, prior approval from the governing agency is required.	N/A
All hydraulic structures are to be constructed according to the <i>Uniform Standard Specifications for Public Works</i> (Maricopa Association of Governments, latest revision).	N/A
The determination of flood hydrology for designing stormwater facilities in Maricopa County is to be performed according to the procedures set forth in the <i>Drainage Design Manual for Maricopa County, Volume I, Hydrology</i> (hereinafter referred to as the <i>Hydrology Manual</i>). Deviations from the procedures in the <i>Hydrology Manual</i> require prior approval from the jurisdictional agency and/or the Flood Control District of Maricopa County before proceeding with the determination of design hydrology.	2-1
According to the <i>Uniform Drainage Policies and Standards for Maricopa County, Arizona</i> (25 February 1987), all development shall make provisions to retain the peak flow and volume of runoff from rainfall events up to and including the 100-year, 2-hour duration storm falling within the boundaries of the proposed development. The criteria to be applied to the 2-hour storm is provided in the <i>Hydrology Manual</i> . Table 2.1 outlines the minimum hydrology design criteria for drainage features.	2-2
Table 2.1: Hydrology Design Criteria	2-3

Recommended Uniform Policy Requirements	Page
All drainageway entrance and exit points in the proposed development must remain in the original location and—as near as possible—in the original condition.	2-4
Table 3.1: Design Storm Frequencies for Street Drainage	3-3
An n value of 0.015 or 0.016 shall be used for street flow unless special conditions exist.	3-6
The allowable carrying capacity for gutters approaching an intersection shall be calculated by applying the reduction factor found in Figure 3.4 to the theoretical capacity. The grade used to determine the reduction factor shall be the same effective grade used to calculate the theoretical capacity.	3-11
The reduction factors contained in Table 3.2 shall be applied to the theoretical catch basin capacity from the curves to obtain the interception capacity used for design.	3-26
All materials used for a storm drain system must be approved by the governing municipality prior to use.	4-4
Storm drain systems shall be designed so that the hydraulic grade line is at least 6 inches below the inlet elevation.	4-4
Culverts for collector and arterial streets are to be designed to convey at least the 50-year peak discharge with no flow crossing over the roadway.	5-3
Culverts for collector and arterial streets are to be designed to convey, at least, the 50-year peak discharge with no flow crossing over the roadway. Additionally, the flow depth over the roadway shall be limited to 0.5 feet for the 100-year peak discharge.	5-4
Possible aggradation or degradation at culvert crossings must be examined in the design of culverts.	5-4

Recommended Uniform Policy Requirements	Page
When any of the following conditions are met, trash racks will be required on the entrances to all conduits in areas of Class A or B hazard as determined from Table 5.2	5-14
<ul style="list-style-type: none"> » When a conduit outfalls into a channel with side slopes steeper than 4(H):1(V) for concrete, grass and earth linings, and 3(H):1(V) for riprap linings. » Conduits smaller than 7 feet in diameter, longer than 100 feet in length, or without 12-inches of freeboard at the design flow rate. » Conduits with energy dissipators at the end. » Conduits being used as outlets from multiple-use detention facilities. » Conduits with sufficient bend that the opposite end cannot be clearly seen. 	
A plugging factor of 50 percent will be used on all trash racks.	5-14
Conditions that will cause trash racks to be used on both inlets and outlets include:	5-14
<ul style="list-style-type: none"> 1. Storm sewers, and 2. Inlets of pipes smaller than 7 feet in diameter that flow into recreation areas that are not designed for pedestrian use. 	
When there is a potential for inlet uplift failure or inlet damage from other sources, concrete headwalls are required on culvert installations unless it can be shown that these dangers do not exist.	5-17
Projecting culvert outlets are not permitted unless approved by the appropriate governing agency.	5-18
A new or replacement bridge will not be permitted to create a rise in the existing water surface elevation, to cause an increase in lateral extent of the floodplain, or to otherwise worsen existing flood conditions.	5-80

Recommended Uniform Policy Requirements	Page
If there is a good possibility of debris collecting on the piers, it may be advisable to use a value greater than the pier width to account for debris blockage. However, modeling of debris blockage should be reviewed with the jurisdictional agency.	5-81
Bridges should be designed to have a minimum freeboard of two feet for the 100-year event. The structural design of the bridge should take into account the possibility of debris and/or flows impacting the bridge.	5-81
For the special condition of supercritical flow within a lined channel, the bridge structure should not affect the flow at all. That is, there should be no projections, piers, etc. in the channel area. The bridge opening should be clear and permit the flow to pass unimpeded and unchanged in cross section.	5-81
If the proposed project will impact Waters of the U.S., the designer shall take into account requirements of the Clean Water Act (CWA), Section 404.	6-2
Design velocities for all linings should not fall below 2 fps to minimize sediment depositional problems.	6-10
Table 6.2: Roadside Channels with Uniform Stand of Various Grass Cover and Well Maintained	6-12
Except as subsequently provided, fencing will be required for all new concrete, shotcrete, and soil cement lined channels with side-slopes steeper than 4:1 that meet a Class A hazard as defined in Table 5.2 (page 5-13). Subcritical channels lined with concrete, shotcrete, and soil cement lined channels having depths and bottom widths less than 3 feet and 5 feet, respectively, will not require fencing. Fencing may be required by individual entities regardless of the conditions listed in this manual.	6-13
Due to erosion and scour of erodible channels and safety concerns with excessively high velocities, the recommended upper limit of F_r is 2.0.	6-17
The Froude Number limit for all types of channel linings is $F_r \leq 0.86$. For concrete, shotcrete, and mortar lined channels, the additional range of $1.13 \leq F_r \leq 2.0$ is allowed. So that flow will be stable F_r should not fall between 0.86 and 1.13.	6-17

Recommended Uniform Policy Requirements	Page
Unless special exception is made by the governing agency, all artificial channels must begin and end where, historically, runoff has flowed.	6-18
For channels with Froude Numbers less than 0.86, the ratio of the channel radius, r_c , (at the centerline) to the design width of the water surface shall be greater than 3.0.	6-20
Required freeboard is computed according to the following formula:	6-21
$FB = 0.25 \left(Y + \frac{V^2}{2g} \right) \quad (6.10)$	
The minimum freeboard value for rigid channels shall be 1 foot for subcritical and 2 feet for supercritical flows. Using a smaller freeboard in specific cases requires prior approval of the governing agency.	
According to ARS 48-3609.A, during the course of the Master Planning process, the 100-year runoff will be used to delineate a floodplain for major channels with discharges of more than 500 cfs and will be processed through the local government, ADWR, and FEMA.	6-26
Encroachments into the floodplain of a natural water course are to be analyzed according to the FEMA requirements.	6-26
At no time should an encroachment adversely affect the stability of a water course or adversely alter flooding conditions on adjacent properties. When encroachment is proposed within the floodplain of a major watercourse, the regulating entity may, at its discretion, request that a detailed study be performed to determine if a reduction in overbank flood storage will significantly affect downstream flood peaks.	6-26
All concrete lined channels must have continuous reinforcement extending both longitudinally and laterally. For channels carrying supercritical flow, there shall be no reduction in cross sectional area at bridges or culverts, or any obstructions in the flow path.	6-35
The minimum thickness of riprap linings shall be the greater of 1.0 times D_{100} or 1.5 times D_{50} .	6-45

Recommended Uniform Policy Requirements	Page
Due to a high failure rate and excessive maintenance costs, drop structures having loose riprap on a sloping face are not permitted.	7-8
Analysis should be conducted for a range of flows, since flow characteristics at the drop can vary with discharge. For example, the 10-year flow may cascade down the face of a sloping drop and form a jump downstream of the toe, whereas the 100-year flow may totally submerge the drop.	7-14
The maximum vertical drop height from crest to basin for a vertical hard basin drop is limited to 3 feet for safety considerations.	7-38
Maximum drop depth for a vertical riprap basin is limited to 3 feet due to safety considerations and the practicality of obtaining large basin riprap for higher drops.	7-42
Designs for hydraulic structures must address the issue of safety. First, signage must be provided to identify the potential hazard of flooding or dangerous flow measures to the public. Second, appropriate measures must be designed to keep the public away from hazardous locations. For example, vertical drop structures should not exceed 3 feet in height, and adequate fencing or railings must be provided along all other walls, such as wing walls or training walls.	7-70
Open channels are recommended in lieu of pipes for conveyance of low flows through the drop structure area. Pipes may plug or frequently overtop, leading to additional maintenance problems. Pipes should be no smaller than 24 inches in diameter.	7-71

Recommended Uniform Policy Requirements	Page
The requirement for a development to provide storage of excess runoff by detention or retention facilities shall not be waived unless determined otherwise by the jurisdictional agency on a case by case basis.	8-3
In general, storage facilities are to be located so they can intercept the flow from the entire development area. If portions of the area cannot drain to a single storage facility, then additional facilities may be added to provide control of those areas as approved by the appropriate jurisdictional agency. The objective is to provide storage of excess runoff with a minimum number of detention/retention facilities located at optimum points within a development area. Whenever possible, the facilities shall be designed for multiple uses, such as parks or other recreational facilities, to offset the cost of open space and to encourage improved maintenance.	
Residential developments shall have no single lot storage and the design of common facilities shall not assume any individual lot on-site storage, unless approved by the jurisdictional agency. Developments with Homeowner's Associations shall locate their facilities in private drainage tracts or public sites dedicated by the developer, in accordance with requirements determined by the jurisdictional agency. The Homeowner's Association will maintain the private facilities, and the jurisdictional agency will usually maintain the public tracts. Common storage facilities from single family developments without a Homeowner's Association and with public streets shall have maintenance provisions determined by the jurisdictional agency. The number and location of storage facilities within a development is to be approved by the jurisdictional agency. Dedication to the public may require the inclusion of recreational facilities or other features deemed necessary by the jurisdictional agency.	
Single lot, non-residential developments that are not served by a public storage facility shall provide the required storage on the lot itself without depressing the right-of-way area.	

Recommended Uniform Policy Requirements	Page
All detention/retention facilities incorporated within new developments shall be designed to retain the peak flow and volume of runoff from the 100-year, 2-hour duration storm event. In the special case of when a detention only facility is allowed, the requirement to retain the 100-year 2-hour runoff volume may be waived. However, the peak discharge requirement must still be met, and the effects of using a detention only facility on more frequent events must be determined.	8-5
Off-site flows may not be routed through a retention facility unless specifically approved by the appropriate jurisdictional agency.	8-5
<i>Side Slopes:</i> Where grass is intended to be established, side slopes shall not be steeper than 4 horizontal to 1 vertical. Where other protection measures are intended, such as shrub planting, rock riprap or other structural measures, slopes shall not exceed 3 horizontal to 1 vertical unless approved by the appropriate jurisdictional agency. Where slopes abut the street right-of-way, the minimum slope shall be 4 horizontal to 1 vertical regardless of surface treatment. Some jurisdictions may require a flatter slope. The designer should verify the slope requirement prior to commencing design.	8-9
<i>Depth and Bottom Configuration:</i> Maximum ponding depth and freeboard requirements vary within Maricopa County and specific criteria for such must be verified by the designer with the appropriate jurisdictional agency. With respect to grading, deep facilities should be avoided, if possible. For facilities with a depth in excess of three feet deep, consideration should be given to the use of flatter side slopes or the provision of intermediate benches along side slopes. The bottom shall be designed to drain to a low flow channel for a detention facility.	8-9
The design of all detention/retention facilities shall be such that the stored runoff shall be discharged completely from the facility within 36 hours after the runoff event has ended.	8-9
The minimum allowable pipe size for primary outlet structures is 12-inches in diameter.	8-12
<i>Trash Racks:</i> Trash racks shall be provided for pipe and orifice outlets.	8-12

Recommended Uniform Policy Requirements	Page
All dry wells must be registered with the Arizona Department of Environmental Quality.	8-15
The pond edge shall be designed to minimize safety hazards. Water depth should be limited to 1.5 to 2 feet within 8 feet of the shoreline.	8-19
The use of rooftops as storage areas for runoff is not permitted in Maricopa County.	8-20
Since the following methods often result in facilities near buildings, it should be emphasized that finished floor elevations of structures shall be a minimum of one foot above the 100-year water surface of the detention/retention facility. The finish floor elevation needs also to be above the emergency outfall of the basin.	8-20
Refer to local jurisdictional standards on the percentage of the parking lot to be used as retention area and the allowable ponded depth. The maximum depth of ponded water within any parking lot location shall be one foot (1 ft). Deeper ponding should be confined to remote areas of parking lots, whenever possible.	8-21
The minimum longitudinal slope permitted within parking lot storage facilities is 0.005 ft/ft, unless concrete valley gutters are provided. With concrete valley gutters, a minimum longitudinal slope of 0.002 ft/ft may be permitted.	8-21
Signs should be provided at all designated entryways of detention/retention facilities. They should also be provided at intervals (approximately 100 feet) around the perimeter of the facility to inform visitors who might gain access at other than designated entrances.	8-27
In addition to entry and perimeter signs, signs should be installed within the facility. These signs should restate the potential flood hazard and should provide directions for appropriate routes out of the basin area should flooding occur.	
Extensive use of herbicides in basins where the primary or secondary purpose is groundwater recharge is not acceptable.	8-32

Recommended Uniform Policy Requirements	Page
Numerous computer software programs (such as HEC-1) have been developed for flood routing through detention/retention facilities. Use of a particular computer program should be approved by the appropriate jurisdictional agency prior to its application on a particular project.	8-40

Hydrology

2.1 Methodology

The determination of flood hydrology for designing stormwater facilities in Maricopa County is to be performed according to the procedures set forth in the *Drainage Design Manual for Maricopa County, Volume I, Hydrology* (hereinafter referred to as the *Hydrology Manual*). Deviations from the procedures in the *Hydrology Manual* require prior approval from the jurisdictional agency and/or the Flood Control District of Maricopa County before proceeding with the determination of design hydrology.

However, it is not the intent of the *Hydrology Manual* to inhibit sound, innovative analysis, or the utilization of superior technology, or the development of improved techniques. Therefore, the investigation, development, and use of the best practical technology for flood hydrology is strongly encouraged in all situations.

The selection of the procedure to use to determine the design flood hydrology is dependent upon the intended application. For small urban watersheds (defined as less than 160 acres and having fairly uniform land use), the use of the Rational Method is acceptable. Use of this method will only produce peak discharges and it should not be used if runoff volume or a complete runoff hydrograph is needed, such as for the routing of flow through a detention/retention facility. For larger, more complex watersheds or drainage networks, a rainfall-runoff model should be developed. The *Hydrology Manual* provides guidance in the development of such a model and the estimation of the necessary input parameters to the model.

Although not necessarily required, the use of the U.S. Army Corps of Engineers' HEC-1 Flood Hydrology Program facilitates the use of the procedures that are contained in the *Hydrology Manual*, which was written to supplement the *HEC-1 User's Manual*.

All of the hydrology that is required for the design of stormwater drainage facilities that

are normally encountered can be performed by using the HEC-1 program; this includes the routing of flood hydrographs through detention/retention structures. The design and performance of pump stations cannot normally be satisfactorily performed using the simplified procedures that are incorporated in the HEC-1 program. Although the inflow hydrograph to a pump station can be adequately developed with HEC-1, the performance and design of pump stations will often require the use of specialized programs.

2.2 Criteria

The *Hydrology Manual* is to be used to develop the design discharge for storms of frequencies up to and including the 100-year event. Table 2.1 of the *Hydrology Manual* lists the different durations to be analyzed depending upon the size of the drainage area. Generally the design storm is of 6-hours duration and is to be used for the design of stormwater drainage facilities except for detention/retention facilities.

According to the *Uniform Drainage Policies and Standards for Maricopa County, Arizona* (25 February 1987), all development shall make provisions to retain the peak flow and volume of runoff from rainfall events up to and including the 100-year, 2-hour duration storm falling within the boundaries of the proposed development. The criteria to be applied to the 2-hour storm is provided in the *Hydrology Manual*. Table 2.1 of this manual outlines the minimum hydrology design criteria for drainage features.

2.3 Master Drainage Planning

According to the *Uniform Drainage Policies and Standards for Maricopa County, Arizona*, master drainage planning shall be done in the earliest stages of the planning process. A master drainage plan incorporates the hydrological analysis for on-site and off-site runoff and outlines the recommended plan for handling storm water runoff.

Master drainage planning can be encountered on both basin-wide and local scales. When undertaking a basin-wide plan, the designer must comprehensively evaluate practical alternatives to find the most cost-effective solution for the general public. Modifications can result from land-use driven decisions that are more costly; however, these additional costs are considered "developer costs" by most agencies. When preparing master drainage plans for local development, the designer shall illustrate conformance with basin-wide master drainage plans where they exist, or shall demonstrate that the plan will not increase extraordinarily the cost of providing basin-wide drainage for the local agency or the District.

Table 2.1
Hydrology Design Criteria

Drainage Feature	Peak Frequencies		
	10 Year	50 Year	100 Year
Street with Curb and Gutter (longitudinal flow)	Runoff contained within street curbs. For collector and arterial streets one 12-foot dry driving lane must be maintained in each direction.	N/A	Runoff to be contained below the finished floor of building. $Q_{max} = 100 \text{ cfs}$ $V_{max} = 10 \text{ fps}$ $d_{max} = 8 \text{ inches}$
Street without Curb and Gutter (longitudinal flow)	Runoff contained within the roadside channels with the water surface elevation below the subgrade.	N/A	Same as Street with Curb and Gutter.
Street with Storm Drain System (longitudinal flow)	Pipes or roadside channels are added if the 10-year runoff exceeds street capacity.	N/A	Storm drains are needed if 100-year runoff inundates the building's finished floor.
Cross Road Culvert for Collector and Arterial Streets	N/A	Runoff to be conveyed by culvert under road with no flow overtopping the road. $V_{max} = 15 \text{ fps}$ $V_{min} = 3.0 \text{ fps}$	Runoff to be conveyed by culvert and by flow over the road with a maximum depth over the road of 6 inches.
FEMA Floodplain Channel ⁽¹⁾	N/A	N/A	100-year peak storm
Channel to Convey Offsite Flow Through Development	N/A	N/A	100-year peak storm
Lowest floor elevation for buildings within a FEMA Floodplain Area	N/A	N/A	Lowest floor elevation to be a minimum of 1 foot above the floodplain water surface elevation.
Lowest floor not in a FEMA Designated Floodplain	N/A	N/A	The lowest floor will be free from inundation for the 100-year peak storm event.
Retention Basin	N/A	N/A	100-year 2-hour storm for determining on-site retention volume.

- (1) Per ARS 48-3609.A, ADWR has established that during the course of the Master Planning process, the 100-year runoff will be used to delineate a floodplain for major channels with discharges more than 500 cfs and should be processed through the local government, ADWR, and FEMA.

The master planning process begins with the conceptual layout of the drainage system, which includes both large and small drainage facilities.

All drainageway entrance and exit points in the proposed development must remain in the original location and—as near as possible—in the original condition.

In many areas about to be urbanized, the runoff has been so minimal that natural channels do not exist. However, surface depressions normally exist and will provide an excellent basis for the initial siting of open channels. This condition is also true for open channels that are to be used primarily for road or highway drainage.

Master plans illustrate selected alternatives, including the footprint of facilities or land uses, approximate sizes, and physical impact on the land. General requirements for structures and their overall size and impacts are also determined during the master planning phase; however, detailed selection of structure types, sizing of riprap, structural design, and selection and detailing of peripheral elements (inlets, trash racks, fencing, etc.) are completed in later phases using the criteria outlined in this manual.

Street Drainage

3.1 Definition of Symbols

The following symbols will be used in equations throughout Chapter 3.

a	=	Gutter depression, inches
A	=	Clear opening area, ft ²
A_g	=	Clear area of the grate, ft ²
C_o	=	Orifice coefficient
C_w	=	Weir coefficient
d	=	Depth at curb measured from the normal cross slope, ft (i.e., $d = TS_x$)
d_i	=	Depth at lip of curb opening, ft
d_o	=	Effective depth at the center of the curb opening orifice, ft
E	=	Hydraulic efficiency of an inlet shorter than the length required for total interception (Q_i/Q)
E_o	=	Ratio of flow in the depressed section to total gutter flow
F_s	=	Gutter capacity reduction factor (see Figure 3.4)
g	=	Gravity, 32.2 ft/s ²
h	=	Height of curb opening catch basin, curb opening orifice, or orifice throat width, ft
L	=	Length of curb opening, grate, or slot, ft
L_T	=	Curb opening length required to intercept 100% of the gutter flow, ft
n	=	Manning's roughness coefficient
P	=	Perimeter of the grate, disregarding bars and side against the curb, ft
Q	=	Total gutter flow, cfs
Q_{cap}	=	Allowable flow rate per gutter, cfs
Q_i	=	Amount of street flow caught by an inlet, cfs
Q_s	=	Flow in paved area, cfs
Q_t	=	Theoretical gutter carrying capacity, cfs
Q_w	=	Flow in width W , ft ³ /s

R_f	=	Ratio of frontal flow intercepted to frontal flow
R_s	=	Ratio of side flow intercepted to total side flow
S	=	Longitudinal street slope, ft/ft
S_e	=	Equivalent cross slope, ft/ft
S_w	=	Cross slope of a depressed gutter, ft/ft
S_w	=	Cross slope of a depressed gutter section measured from the normal cross slope of the pavement, (a/W) , ft/ft
S_x	=	Pavement cross slope, ft/ft
T	=	Allowable spread, ft
V	=	Velocity of flow in the gutter, ft/s
V_o	=	Gutter velocity where splash-over first occurs (see Figure 3.27), ft/s
W	=	Width of depression, depressed gutter or grate, or slot, ft
y	=	Depth of flow, ft
z	=	Reciprocal of the pavement cross-slope, $1/S_x$, ft/ft

3.2 Streets

Urban streets with curbs and gutters serve as an important and necessary drainage service, even though their primary function is for the movement of traffic. Traffic and drainage uses are compatible up to a point, beyond which drainage is, and must be, subservient to traffic needs.

Gutter flow in streets is necessary to transport runoff water to catch basins and to major drainage channels. Good planning of streets can substantially help in reducing the size of, and sometimes eliminate the need for, a storm drain system in newly urbanized areas.

An overall approach to storm runoff management includes using the street system to transport runoff to catch basins and to transport runoff from storms that are greater than the storm drain capacity.

Freeways and similar types of roadways are not addressed in this manual.

3.2.1 Design Criteria for Streets and Gutters

3.2.1.1 Design Frequency: Storm drainage within a street system serves two primary objectives:

1. Remove nuisance flows from pavement during frequent return period storms to maintain safe and efficient movement of traffic.
2. Protect adjacent properties from damage caused by large, infrequent storms.

Table 3.1
Design Storm Frequencies for Street Drainage⁽¹⁾

Longitudinal Street Flow	Event ⁽²⁾
No curb overtopping. Maintain one dry 12-foot driving lane in each direction for collector and arterial streets.	10 year
Flow to be calculated assuming contained between buildings with: 100 cfs maximum flow. 10 fps maximum velocity. Maximum depth of 8 inches.	100 year

- (1) No new inverted crown streets.
(2) Some cities might use a different design event.

The function of removing nuisance flows from pavement is based on providing storm drain catch basins at points where maximum depth or driving lane inundation criteria are reached.

Storm drain system design is based on the design storm. The design storm is the storm associated with the governing return period for longitudinal street flow from Table 3.1. In the upper reaches of a system the 10-year criteria will govern. Farther downstream in the system, the storm drain system design for the 10-year storm may not meet the criteria stated for the 100-year storm. Storm drains will then need to be upsized to meet the 100-year criteria. Both return periods need to be checked to determine which condition governs. The storm condition governing design at any point is the design storm.

3.2.1.2 Pavement Encroachment: The following sections present specific design requirements for storm drainage on urban type streets for the design storm. Typical street sections used in Maricopa County are presented in Figure 3.1. Determination of street carrying capacity for the design storm shall be based upon two considerations:

1. Pavement encroachment and depth for computed theoretical flow conditions.
2. An empirical reduction of the theoretical allowable rate of flow to account for practical field conditions.

The storm drain system should commence at or prior to the point where the maximum encroachment and/or depth is reached, and should be designed on the basis of the design storm. The final design must meet both the 10-year and 100-year criteria set forth in Table 3.1.

The preceding criteria is established for new construction. Changes to an existing system, or a retrofit situation may not be able to meet the 10-year criteria, however, any changes to a system should meet the 100-year storm criteria.

Figure 3.1
Typical Street Cross Section

$$Q = \left(\frac{0.56}{n} \right) S_x^{1.67} S^{0.5} T^{2.67}$$

Example:

Given:

$$n = 0.016 \quad S_x = 0.03$$

$$S = 0.04 \quad T = 6 \text{ ft}$$

Find:

$$Q = 2.4 \text{ ft}^3/\text{s}$$

$$Qn = 0.038 \text{ ft}^3/\text{s}$$

Figure 3.2
Nomograph for Triangular Gutters
(USDOT, FHWA, 1984, HEC-12, Chart 3)

3.2.1.3 Theoretical Capacity: When the allowable pavement encroachment has been determined, the theoretical gutter carrying capacity shall be computed using the modified Manning's formula for flow in a shallow triangular channel, as shown in Figure 3.2 or as expressed in Equation 3.1:

$$Q_t = \left(\frac{0.56}{n} \right) S_x^{1.67} S^{0.5} T^{2.67} \quad (3.1)$$

Using $d = TS_x$ and $z = 1/S_x$ Equation 3.1 can be expressed as:

$$Q_t = 0.56 \left(\frac{z}{n} \right) S^{1/2} d^{8/3} \quad (3.2)$$

Typical gutter configurations from Maricopa Association of Governments (MAG) are shown in Figure 3.3. Figure 3.2 may be used for all gutter configurations. To simplify computations, graphs for particular street shapes may be plotted.

An n value of 0.015 or 0.016 shall be used for paved streets unless special conditions exist.

3.2.1.4 Reduction Factors: The gutter capacity from Figure 3.2 is based on the theoretical capacity of a clean, unobstructed, continuous gutter section. In reality, parked car tires in the gutter and debris cause obstructions to flow. Driveways, alleys, and curb cuts cause discontinuities in the flow. When water flowing in a gutter encounters an obstruction or discontinuity, it is deflected out of the gutter into the street section or onto the sidewalk. If the velocity is high enough, the flow diverted out of the gutter will flow across the street crown to the gutter on the opposite side. If an inlet is located just downstream of the obstruction the water will flow past the inlet without being intercepted. Gutter capacity reduction factors are established to limit velocities and reduce the lane encroachment caused by water deflected into the street and to allow adequate capacity for unanticipated inlet bypass flows caused by obstructions.

The actual flow rate allowable in the gutter is to be calculated using Equation 3.3, in which the theoretical capacity is multiplied by the corresponding reduction factor (F_s) obtained from Figure 3.4. Discharge curves can be developed for standard streets by plotting the solution of Equation 3.3 for a range of longitudinal slopes using the appropriate gutter capacity reduction factor, F_s , and the theoretical gutter capacity computed for each slope.

$$Q_{cap} = F_s Q_t \quad (3.3)$$

Figure 3.3
Detail for Curbs and Gutters
 (Adapted from MAG Standards)

Figure 3.4
Gutter Capacity Reduction Factors

3.2.1.5 Transition at Curb and Gutter End: Where curb and gutter sections end, care must be taken to transition the gutter flow into the receiving ditch or channel to prevent scour. When the flow encounters a widening in the channel cross section, it spreads at approximately 4:1 (longitudinal to transverse). A concrete or rock riprap apron should be provided to protect the receiving channel or ditch, and to spread the flow until the velocity is below the maximum allowable velocity for the channel material. The protection must be placed far enough below the flowline so that there are no adverse impacts from ponding or siltation.

3.2.2 Design Criteria for Intersections

Figure 3.5 is a typical illustration of the variations in grade when local streets intersect. When local streets intersect arterial or collector streets, the grades of the arterial or collector street should be continued uninterrupted.

When collector and arterial streets intersect, the grade of the more major street should be maintained as much as possible. For drainage purposes, no form of valley gutter should be constructed across an arterial street. Infrequently, with agency approval, valley gutters may be considered on collector streets.

Conventional valley gutters may be used to transport runoff across local streets when a storm drain system is not required *and* when approved by the governmental agency. The valley gutter should be sufficient to transport the runoff across the intersection with encroachment equivalent to that allowed on the street.

3.2.2.1 Theoretical Capacity: The theoretical carrying capacity of each gutter approaching an intersection shall be calculated based upon the effective slope, as outlined herein.

Continuous Grade Across Intersection: When the gutter slope will be continued across an intersection—as when valley gutters are in place—use the slope of the gutter flow line crossing the street to calculate capacity.

Flow Direction Change at Intersection: When the gutter flow must undergo a direction change at the intersection greater than 45 degrees, the slope used for calculating capacity shall be the effective gutter slope, defined as the average of the gutter slopes at 0 feet, and 50 feet upstream from the point of direction change.

Flow Interception by Inlet: When the gutter flow is intercepted by an inlet on continuous grade at the intersection, the effective gutter slope shall be utilized for calculations. Under this condition, the points for averaging shall be 0 feet, 25 feet, and 50 feet upstream from the inlet.

Local Street to Local Street

Local or Collector to Arterial

Arterial to Arterial
(Where Crowns are to be Maintained)

Arterial to Arterial
(One Continuous Crown)

These examples show the minimum required inlets.
Additional inlets may be necessary based upon
allowable carrying capacity of gutters.

Figure 3.5
Typical Street Intersection
Drainage to Storm Drain System

3.2.2.2 Allowable Capacity:

The allowable carrying capacity for gutters approaching an intersection shall be calculated by applying the reduction factor found in Figure 3.4 to the theoretical capacity. The grade used to determine the reduction factor shall be the same effective grade used to calculate the theoretical capacity.

Special Considerations for Business Areas and Heavily-used Pedestrian Areas: In highly concentrated business areas where large volumes of pedestrian traffic are likely, consider using walk-over curbs (where the pavement grade is raised to match the curb elevation at the crosswalk) at intersections. If used, however, two catch basins would be required at nearly every corner as flow may not be allowed to continue around the corner. For the storm frequency being contemplated, the effect water may have on pedestrian walking area should be compatible with that on streets. Based upon vehicular traffic use in a business area all streets would probably be classified as collector or arterial, requiring a minimum of one water-free travel lane in each direction. The walk-over curbs should be available for limited pedestrian use.

Where concentration of pedestrians occurs, depth and area limitations may need modifications. As an example, streets adjacent to schools are arterials from a pedestrian standpoint and should be designed accordingly. Designing for pedestrian traffic is as important as designing for vehicular traffic. Ponding water and gutter flow wider than two feet is difficult for pedestrians to negotiate.

Where business buildings are constructed to property lines, the reduced clearance between buildings and heavy traffic must be considered. Splash from vehicles striking gutter flow may damage store fronts and make walking on sidewalks difficult.

Although not a necessity in many business areas, highly concentrated business areas should be designed to use reduced allowable pavement encroachment area and inundated areas, raised walk-over curbs at intersections, or additional catch basins to intercept flow before it reaches intersections. Generally, storm drains should be installed in these areas even if other criteria do not so indicate.

3.2.3 Design Criteria for Roadside Ditches

Roadside ditches are commonly used in rural areas to convey runoff from the highway pavement, and from areas which drain toward the highway. Where practicable, the flow from major areas draining toward curbed highway pavements should be intercepted by ditches.

The following criteria pertain to the design of open channels along roadsides. For additional criteria for open channels, see Chapter 6.

3.2.3.1 Permissible Use: Roadside ditches adjacent to public streets are discouraged in urban areas and require approval from the governing municipality. When they are allowed, adhere to the criteria outlined in this section.

3.2.3.2 Street Capacity for the Design Storm: Depth of flow in roadside ditches for the design storm shall be limited to preclude saturation of the adjacent roadway subgrade. Where curbs exist and roadside ditches are used in lieu of storm drains, catch basins or scuppers should be provided as needed to drain the pavement into the drainage ditch while meeting the criteria set forth in Table 3.1.

3.2.3.3 Geometry: Geometric considerations in the design of channel cross-sections should incorporate hydraulic requirements for the design discharge, safety, minimization of right-of-way acquisition, economy in construction and maintenance, and good appearance.

Channel side slopes should be as mild as practical and should be no steeper than 4:1 where terrain and right-of-way permit. The advantages of mild slopes are that the potential for erosion and slides is lessened, maintenance is eased, and the safety of errant vehicles is enhanced. Safety considerations are subject to the requirements of the local jurisdiction.

Trapezoidal channel bottoms should be a minimum of 4-feet wide for maintenance purposes. V-shaped channels may also be used when approved by the governing municipality.

Local soil conditions, flow depths, and velocities within the channel are usually the primary hydraulic considerations in channel geometric design; however, terrain and safety considerations have considerable influence. Steeper side slopes of rigid, lined channels may be more economical and will improve the hydraulic flow characteristics. The use of steeper slopes is normally limited to areas with limited right-of-way where the hazard to traffic can be minimized through the use of guardrails or parapets.

3.2.3.4 Rural Crown Ditch: In mountainous terrain where large cuts are required, crown ditches constructed on top of the cut embankment will intercept runoff preventing it from eroding the face of the cut slope. A typical crown ditch is shown in Figure 3.6.

Figure 3.6
Crown Ditch

3.3 Catch Basins

Proper surface drainage of streets and highways may require intercepting excess flows with stormwater catch basins. A stormwater inlet or catch basin is an opening into a storm drain system to permit entrance of surface storm runoff. The most upstream catch basin in the system should be placed as far downstream as possible, because as soon as the runoff enters the pipe system, it is carried rapidly downstream which tends to reduce the time of concentration. The placing of catch basins is dictated by street encroachment and flow depth criteria (see Table 3.1).

3.3.1 Catch Basin Types

There are four categories of catch basins:

- ▶ curb opening catch basins
- ▶ grated catch basins
- ▶ combination catch basins
- ▶ slotted drain catch basins

Catch basins may be further classified as being on a continuous grade or in a sump. The *continuous grade* condition exists when the street grade is continuous past the catch basin and the water can flow past. The *sump condition* exists whenever water is restricted to the catch basin area because the catch basin is located at a low point. This may be due to a change in grade of the street from positive to negative or due to the crown slope of a cross street when the catch basin is located at an intersection.

Two or more catch basins placed close to each other may act as one hydraulic unit.

3.3.1.1 Curb Opening Catch Basins: Curb opening catch basins (Figure 3.7a) are best for use when a sump condition exists. Although a curb opening catch basin will not guarantee against plugging by debris, it is the most desirable type of catch basin.

A curb opening catch basin is a vertical opening in a curb through which the gutter flow passes. For safety reasons, the vertical opening should not be greater than 6 inches. The gutter may be undepressed or depressed in the area of the curb opening. The capacity of the curb opening is significantly increased by depressing the opening. Permissible curb opening catch basins are contained in the Maricopa Association of Governments (MAG) Standard Details. All details and inlet types must be approved by the governing municipality. A characteristic of the curb opening catch basin is its relative inefficiency on streets of steep grade. Therefore, curb opening catch basins less than 5 feet in length shouldn't be used on steep grades. However, longer catch basins can be quite efficient and should be considered for use on streets with slopes up to 1.0 percent.

(b) Grated Catch Basin Inlet

(c) Combination Catch Basin Inlet

(d) Slotted Drain Catch Basin Inlet

Figure 3.7
Catch Basin Inlets

3.3.1.2 Grated Catch Basin: Grated or gutter catch basin refers to an opening in the gutter covered by one or more grates through which the water falls (see Figure 3.7b). As with other catch basins, grated catch basins may be either depressed or undepressed and are more efficient than curb opening catch basins when located on a continuous grade. Permissible grated catch basins are contained in the MAG Standard Details. Other details must be approved by the governing municipality.

When grated catch basins are used, the engineer should design them to optimize hydraulic efficiency, bicycle and pedestrian safety, structural adequacy, economy, and freedom from clogging (see *Combination Catch Basin* for recommendations).

3.3.1.3 Combination Catch Basin: A combination catch basin is composed of a curb opening and a grated catch basin acting as a unit (see Figure 3.7c). Usually the gutter opening is placed adjacent to the curb opening. As with other catch basins, a combination catch basin may be either depressed or undepressed and located in a sump or on a continuous grade.

For the widest range of conditions, the combination catch basin is the most efficient type of stormwater catch basin for hydraulic interception capabilities and eliminating debris clogging. Permissible combination catch basins are contained in the MAG Standard Details. Other details must be approved by the governing municipality.

3.3.1.4 Slotted Drain Catch Basins: A slotted drain (Figure 3.7d) is a slot opening in the pavement which intercepts sheet flow and conveys it through a corrugated steel pipe. Slotted drains are most effective when street slopes are shallow.

3.3.2 Catch Basin Applications

The following general recommendations are made for different types of stormwater catch basins.

3.3.2.1 Sump Conditions:

True Sump: Depressed curb opening catch basins are recommended for true sump conditions. Each true sump should be reviewed to determine if the area affected by ponding is within acceptable limits. The ponding caused by the 100-year flow should also be checked to assure that the 100-year inundation criteria in Tables 2.1 and 3.1 are met. True sumps should be designed with care, considering the flow path that will be taken by flows in excess of the design flow. In some cases a drainage easement may be necessary to prevent damage to adjacent property during storms in excess of the design storm or in case of total blockage of the inlet by debris. Placement of an inlet should not make conditions worse than they were before. This is an important consideration in retrofit situations.

Sumps Formed by Crown Slope of Cross-Street at Intersection: Curb opening catch basins are recommended for these conditions, although combination catch basins may be used successfully. Conditions need to be checked to prevent a small amount of ponding from causing excessive lane encroachment or storm runoff flowing over the crown of the cross street and continuing down the gutter.

3.3.2.2 Continuous Grade Conditions: Curb opening catch basins should be used on continuous grades, unless otherwise approved by the governing municipality. Inlet spacing should be limited to a maximum of 660 feet for collection of nuisance flows.

3.3.2.3 Shallow Sheet Flow Condition: Slotted drains may be used as permitted by the governing municipality.

3.3.2.4 Large Inlet Inflows: In areas where large inflows are admitted into the storm drain system, hazards may be introduced to vehicular and pedestrian traffic due to large depths and velocities. Special consideration should be given to design of large inlet facilities. When possible, large inlet facilities should be located off of the roadway and provided with trash racks and fencing to improve safety.

3.3.3 Allowable Catch Basin Capacities

The inlet capacity reduction factors, also called clogging factors, outlined in Table 3.2 should be applied to the theoretical calculated capacity of catch basins based upon their type and function. The reduction factors compensate for effects which decrease the capacity of the catch basin such as debris plugging, pavement overlaying, and in variations of design.

The allowable capacity of a catch basin should be determined by applying the applicable factor from Table 3.2 to the theoretical capacity calculated in accordance with the appropriate design charts.

The percentage of theoretical capacity allowed may be even lower when the catch basin is likely to intercept large amounts of sediment or debris. For instance, the first catch basin to a pipe network draining a high debris-yielding area may actually accept only 20 percent of the theoretical capacity allowed because of clogging. Sediment traps should not be designed into the catch basin. A sediment trap formed by lowering the floor of the catch basin below the elevation of the outlet pipe is unnecessary and undesirable since there is too much turbulence for effective trapping at design flow rates, and cleaning is costly. Catch basins should be self-scouring, even under low-flow conditions.

Table 3.2
Reduction Factors to Apply to Catch Basins

Condition	Inlet Type	Reduction Factor
Sump	Curb Opening	0.80
Sump	Grated	0.50
Sump	Combination	0.65
Continuous Grade	Curb Opening	0.80
Continuous Grade	Longitudinal Bar Grate	0.75
	Longitudinal Bar Grate with recessed transverse bars	0.60
Continuous Grade	Combination ⁽¹⁾	Apply factors separately to grate and curb opening
Shallow Sheet Flow ⁽²⁾	Slotted Drains	0.80

(1) See Section 3.3.4.3, Combination Catch Basins

(2) Slotted drains are most effective for shallow sheet flow conditions. With greater depths and flows, a different type of inlet should be used.

3.3.4 Catch Basin Design Procedures

Figures 3.9 to 3.19 (pages 3-27 to 3-37) are capacity curves for standard catch basins. When designing a *nonstandard* catch basin, use the equations and procedures outlined herein. The approval of the governing municipality should be obtained before designing a nonstandard catch basin. The procedures and equations in this section are adapted from the Federal Highway Administration Hydraulic Engineering Circular No. 12 (HEC-12), *Drainage of Highway Pavements* (USDOT, FHWA, 1984). Refer to Section 3.1 for definitions of coefficients used in the following equations.

3.3.4.1 Curb Opening Catch Basins:

On-Grade: The length of curb opening catch basin required for total interception of gutter flow on a pavement section with a straight cross slope is expressed as:

$$L_T = 0.6Q^{0.42}S^{0.3}\left(\frac{1}{nS_x}\right)^{0.6} \quad (3.4)$$

Figure 3.20 (page 3-38) is a nomograph for the solution of Equation 3.4.

The efficiency of curb opening catch basins shorter than the length required for total interception is:

$$E = 1 - \left(1 - \frac{L}{L_T}\right)^{1.8} \quad (3.5)$$

Figure 3.21 (page 3-39) provides a solution of Equation 3.5 and the equation is applicable with either straight cross slopes or compound cross slopes.

The length of catch basin required for total interception by depressed curb opening catch basins or curb openings in depressed gutter sections can be found by using an equivalent cross slope, S_e , in Equation 3.4.

$$S_e = S_x + S'_w E_o \quad (3.6)$$

E_o is the ratio of flow in the depressed section to the total gutter flow, and S'_w is the cross slope of the gutter measured from the cross slope of the pavement, S_x . Figure 3.22 (page 3-40) can be used to determine the spread, and then Figure 3.23 (page 3-41) can be used to determine E_o .

The length of curb opening required for total interception can be significantly reduced by increasing the cross slope or the equivalent cross slope. The equivalent cross slope can be increased by use of a continuously depressed gutter section or a locally depressed gutter section.

Using the equivalent cross slope, S_e , Equation 3.4 becomes:

$$L_T = 0.6Q^{0.42} S^{0.3} \left(\frac{1}{nS_e}\right)^{0.6} \quad (3.7)$$

Figures 3.20 and 3.21 are applicable to depressed curb opening catch basins using S_e rather than S_x .

Sumps: The capacity of a curb opening catch basin in a sump depends on water depth at the curb, the curb opening length, and the height of the curb opening. The catch basin operates as a weir for depths of water up to the curb opening height and as an orifice at depths greater than 1.4 times the opening height. At water depths between 1.0 and 1.4 times the opening height, flow is in a transition stage.

The weir location for a depressed curb opening catch basin is at the edge of the gutter, and the effective weir length is dependent on the width of the depressed gutter and the length of the curb opening. The weir location for a curb opening catch basin that is not depressed is at the lip of the curb opening, and its length is equal to that of the catch basin. Limited experiments and extrapolation of the results of tests on depressed catch basins indicate that the weir coefficient for curb opening catch basins without depression is approximately equal to that for a depressed curb opening inlet.

The equation for the interception capacity of a depressed curb opening catch basin operating as a weir is:

$$Q_i = C_w (L + 1.8W) d^{1.5} \quad (3.8)$$

where $C_w = 2.3$.

The weir equation is applicable to depths at the curb approximately equal to the height of the opening plus the depth of the depression. Thus, the limitation on the use of Equation 3.8 for a depressed curb opening catch basin is:

$$d \leq h + \frac{a}{12}$$

Experiments have not been conducted for curb opening catch basins with a continuously depressed gutter, but it is reasonable to expect that the effective weir length would be as great as that for a catch basin in a local depression. Use of Equation 3.8 will yield conservative estimates of the interception capacity.

The weir equation for curb opening catch basins without depression ($W = 0$) becomes:

$$Q_i = C_w L d^{1.5} \quad (3.9)$$

where $C_w = 3.0$.

The depth limitation for operation as a weir becomes: $d \leq h$.

Curb opening catch basins operate as orifices at depths greater than approximately 1.4h. The interception capacity can be computed by Equation 3.10:

$$Q_i = C_o h L (2 g d_o)^{0.5} \quad (3.10)$$

where $C_o = 0.67$.

Equation 3.10 is applicable to depressed and undepressed curb opening catch basins and the depth at the catch basin includes any gutter depression.

Height of the orifice in Equation 3.10 assumes a vertical orifice opening. As illustrated in Figure 3.8, other orifice throat locations can change the effective depth on the orifice and the dimension ($d_i - h/2$). A limited throat width could reduce the capacity of the curb opening catch basin by causing the catch basin to go into orifice flow at depths less than the height of the opening.

Figure 3.24 (page 3-42) provides solutions for Equations 3.8 and 3.10 for depressed curb opening catch basins, and Figure 3.25 (page 3-43) provides solutions for Equations 3.9 and 3.10 for curb opening catch basins without depression. Figure 3.26 (page 3-44) is provided for use for curb openings with inclined or vertical orifice throats.

3.3.4.2 Grated Catch Basins:

On-Grade: Grated catch basins intercept all of the frontal flow until “splash over” (the velocity at which water begins to splash over the grate) is reached. At velocities greater than splash over, grate efficiency in intercepting frontal flow is diminished. Grates also intercept a portion of the flow along the length of the grate, or the side flow, dependent on the cross slope of the pavement, the length of the grate, and flow velocity.

The ratio of frontal flow to total gutter flow, E_o , for a straight cross slope is:

$$E_o = \frac{Q_w}{Q} = 1 - \left(1 - \frac{W}{T}\right)^{2.67} \quad (3.11)$$

Figure 3.23 (page 3-41) provides a graphical solution of E_o for either straight cross slopes or depressed gutter sections.

Figure 3.8
Curb Opening Catch Basin Inlets
 (modified from: USDOT, FHWA, 1984, HEC-12, Figure 21)

The ratio of side flow, Q_s , to total gutter flow is:

$$\frac{Q_s}{Q} = 1 - \frac{Q_r}{Q} = 1 - E_o \quad (3.12)$$

The ratio of frontal flow intercepted to total frontal flow, R_f , is expressed:

$$R_f = 1 - 0.09(V - V_o) \quad (3.13)$$

This ratio is equivalent to frontal flow interception efficiency. Figure 3.27 (page 3-45) provides a solution of Equation 3.13 which takes into account grate length, bar configuration and gutter velocity at which splash-over occurs. The gutter velocity needed to use Figure 3.27 is total gutter flow divided by the area of flow.

The ratio of side flow intercepted to total side flow, R_s , or side flow interception efficiency, is:

$$R_s = \frac{1}{\left(1 + \frac{0.15 V^{1.8}}{S_x L^{2.3}}\right)} \quad (3.14)$$

Figure 3.28 (page 3-46) provides a solution of Equation 3.14.

A deficiency in developing empirical equations and charts from experimental data is evident in Figure 3.28. The fact that a grate will intercept all or almost all of the side flow where the velocity is low and the spread only slightly exceeds the grate width is not reflected in the figure. Error due to this deficiency is very small. In fact, where velocities are high, side flow interception can be neglected entirely without significant error.

The efficiency, E , of a grate is:

$$E = R_f E_o + R_s (1 - E_o) \quad (3.15)$$

The first term on the right side of Equation 3.15 is the ratio of intercepted frontal flow to total gutter flow, and the second term is the ratio of intercepted side flow to total side flow. The second term is insignificant with high velocities and short grates.

The interception capacity of a grate catch basin on grade is equal to the efficiency of the grate multiplied by the total gutter flow:

$$Q_i = EQ = Q[R_f E_o + R_s(1 - E_o)] \quad (3.16)$$

Sumps: The efficiency of catch basins in passing debris is critical in sump locations because all runoff which enters the sump must be passed through the catch basin. Total or partial clogging of catch basins in these locations can result in hazardous ponding conditions. Grate catch basins alone are not recommended for use in sump locations because of the tendencies of grates to become clogged. Combination catch basins or curb-opening catch basins are recommended for use in these locations.

A grate catch basin in a sump location operates as a weir to depths dependent on the bar configuration and size of the grate and as an orifice at greater depths. Grates of larger dimension and grates with more open area, i.e., (with less space occupied by lateral and longitudinal bars), will operate as weirs to greater depths than smaller grates or grates with less open area.

The capacity of grate catch basins operating as weirs is:

$$Q_i = C_w P d^{1.5} \quad (3.17)$$

where $C_w = 3.0$.

The capacity of a grate catch basin operating as an orifice is:

$$Q_i = C_o A (2gd)^{0.5} \quad (3.18)$$

where $C_o = 0.67$.

Use of Equation 3.18 requires the clear opening area of the grate. Tests of three grates for the Federal Highway Administration showed that for flat bar grates, such as P-1-7/8-4 and P-1-1/8 grates, the clear opening is equal to the total area of the grate less the area occupied by longitudinal and lateral bars.

Figure 3.29 (page 3-47) is a plot of Equations 3.17 and 3.18 for various grate sizes. The effects of grate size on the depth at which a grate operates as an orifice is apparent from the chart. Transition from weir to orifice flow results in interception capacity less than that computed by either the weir or the orifice equation. This capacity can be approximated by drawing in a curve between the lines representing the perimeter and net area of the grate to be used.

3.3.4.3 Combination Catch Basins:

On-Grade: The interception capacity of a combination catch basin consisting of a curb opening and grate placed side-by-side is not appreciably greater than that of the grate alone. Capacity is computed by neglecting the curb opening. A combination catch basin is sometimes used with the curb opening or a part of the curb opening placed upstream of the grate. The curb opening in such an installation intercepts debris which might otherwise clog the grate and has been termed a "sweeper" by some. A combination catch basin with a curb opening extending upstream of the grate has an interception capacity equal to the sum of the grated catch basin and the portion of the curb opening inlet upstream of the grate. The frontal flow and thus the interception capacity of the grate is reduced by the flow intercepted by the curb opening.

Sump: Combination catch basins consisting of a grate and a curb opening are considered advisable for use in sumps where hazardous ponding can occur. The interception capacity of the combination catch basin is essentially equal to that of a grate alone in weir flow unless the grate opening becomes clogged. In orifice flow, the capacity is equal to the capacity of the grate plus the capacity of the curb opening.

Equation 3.17 or Figure 3.29 can be used for weir flow in combination catch basins in sump locations. Assuming complete clogging of the grate, Equations 3.8, 3.9, and 3.10, or Figures 3.24, 3.25, and 3.26 for curb-opening catch basins are applicable.

Where depth at the curb is such that orifice flow occurs, the interception capacity of the catch basin is computed by adding Equations 3.18 and 3.10:

$$Q_i = 0.67A_g(2gd)^{0.5} + 0.67hL(2gd_o)^{0.5} \quad (3.19)$$

Trial and error solutions are necessary for depth at the curb for a given flow rate using Figures 3.24, 3.25, 3.26, or 3.29 for orifice flow.

3.3.4.4 Slotted Drain Catch Basins:

On-Grade: Wide experience with the debris handling capabilities of slotted drain catch basins is not available. Deposition in the pipe is the problem most commonly encountered; however, the catch basin is accessible for cleaning with a high pressure water jet.

Slotted drain catch basins are effective pavement drainage catch basins which have a variety of applications. They can be used on curbed or uncurbed sections and offer little interference to traffic operations.

Flow interception by slotted drain catch basins and curb opening catch basins is similar in that each is a side weir and the flow is subjected to lateral acceleration due to the cross slope of the pavement. Analysis of data from the HEC-12 tests of slotted drain catch basins with slot widths greater than or equal to 1.75 inches indicates that the length of the slotted drain catch basin required for total interception can be computed using Equation 3.4. Figure 3.20 is therefore applicable for both curb opening catch basins and slotted drain catch basins. Similarly, Equation 3.5 is also applicable to slotted drain catch basins and Figure 3.21 can be used to obtain the catch basin efficiency for the selected length of the catch basin.

Using Figures 3.20 and 3.21 for slotted drain catch basins is the same as using them for curb opening catch basins. It should be noted, however, that it is much less expensive to add length to a slotted drain catch basin to increase interception capacity than it is to add length to a curb opening catch basin.

Sump: Slotted drain catch basins in sump locations perform as weirs to depths of about 0.2 ft, dependent on slot width and length. At depths greater than about 0.4 ft, they perform as orifices. Between these depths, flow is in a transition stage. The interception capacity of a slotted drain catch basin operating as an orifice can be computed by Equation 3.20:

$$Q_i = 0.8 L W (2gd)^{0.5} \quad (3.20)$$

where: d = depth of water at slot, ft
 $d \geq 0.4$ ft

Equation 3.20 becomes:

$$Q_i = 0.94 L d^{0.5} \quad (3.21)$$

where: $W = 1.75$ "

The interception capacity of slotted drain catch basins at depths between 0.2 and 0.4 feet can be computed by using the orifice equation. The orifice coefficient varies with depth, slot width, and the length of the slotted drain catch basin.

Figure 3.30 (page 3-48) provides the solutions for weir flow, transition flow and orifice flow.

3.3.5 Design Aids

The inlet capacity curves in Figures 3.9 - 3.19 have been developed using procedures set forth in HEC-12 and are to be used for selecting Standard MAG inlets for pavement drainage design in Maricopa County. The curves are developed for a street cross slope of two percent and do not include reduction factors to account for plugging.

The reduction factors contained in Table 3.2 shall be applied to the theoretical catch basin capacity from the curves to obtain the interception capacity used for design.

Figures 3.20 - 3.30 are from HEC-12 and are provided here as additional aids in the sizing of inlets. Refer to HEC-12 for design examples and inlet location procedures.

Storm Drains

4.1 Definition of Symbols

α	=	The central angle of the bend, degrees
θ	=	The horizontal angle of divergence or convergence between two sections, degrees
A	=	Area of water normal to flow, ft ²
D	=	Diameter of storm drain, ft
E	=	Specific energy, ft
g	=	Acceleration due to gravity, 32.2 ft/sec ²
h_b	=	Head loss due to a bend, ft
h_f	=	Head loss due to friction, ft
h_j	=	Head loss due to a junction, ft
h_{mh}	=	Head loss due to a manhole, ft
h_{minor}	=	Minor head losses, ft
h_t	=	Head loss due to transition (contraction or expansion) in pipe size, ft
k_b	=	Bend loss coefficient
k_c	=	Coefficient for transition loss due to contraction of flow
k_e	=	Coefficient for transition loss due to expansion of flow
k_j	=	Junction loss coefficient
L	=	Horizontal length of a storm drain, ft
n	=	Manning's roughness coefficient
Q	=	Rate of flow, ft ³ /sec
r	=	Radius of curvature, ft
R	=	Hydraulic radius, ft
S_f	=	Friction slope, ft/ft
S_o	=	Invert slope, ft/ft
T_c	=	Time of concentration, min.
V	=	Velocity, ft/s
Y	=	Vertical distance from invert to hydraulic grade line, ft

4.2 Storm Drains

In this manual, storm drain system refers to the system of inlets, conduits, manholes, and other appurtenances which are designed to collect and convey storm runoff from the design storm to a point of discharge and into a major or regional drain outfall. Storm drain system design is based on the design storm. The design storm is the storm associated with the governing return period from Table 3.1, (page 3-3). In the upper reaches of a system the 10-year criteria will govern. Farther downstream in the system, the storm drain system design for the 10-year storm may not meet the criteria stated for the 100-year storm. Storm drains will then need to be upsized to meet the 100-year criteria. Both return periods need to be checked to determine which condition governs. The storm condition governing design at any point is the design storm.

The designer of the storm drain system will have to use good professional judgement when dealing with the conflicts that can occur with existing utilities. When the designer has to deviate from the requirements of this chapter, they should contact the governing municipality as soon as possible to explain the situation and come to an agreement on the solution.

4.2.1 Interaction of Storm Drain Systems with other Systems

Storm drains will generally only work for minor water courses. Storm drains typically are not economical for the flows conveyed within larger water courses. Therefore, the storm drain system will collect runoff to a point where storm drains become too large to be economical and will then discharge into a major or regional watercourse outfall consisting of a man-made channel, natural wash, or river.

4.2.2 Storm Drain Criteria

4.2.2.1 Maximum Velocity: Consideration should be given to possible pipe damage, the flow energy and how the system hydraulics will be affected. Large momentum forces are generated when high velocity flow is directed around bends and transitions. The conditions at the storm drain outlet should also be considered.

4.2.2.2 Minimum Velocity: Since conduits generally are designed on the basis of their capacity when flowing full, or nearly full, the provision of a velocity adequate for self-cleansing under these conditions does not necessarily ensure prevention of deposits at all conditions of flow. Research shows that full flow in a pipe with a Darcy-Weisbach friction factor of 0.025, at 2 ft/s, will barely move a coarse sand particle with a diameter of 1.8 mm. As the friction factor increases, the scouring velocity decreases. Since the friction factor increases with decreasing depth of flow in a pipe, equal self-cleansing will occur in partially full pipes at somewhat less than the critical velocity when flowing full. Equal cleansing ability is computed based on the critical tractive force required to move

a particle through the pipe. Where possible, a minimum cleansing velocity of 5 ft/s shall be maintained in the system. However, a minimum velocity of 2 ft/s must be maintained when flow is one-half of the design discharge.

4.2.2.3 Minimum Slope: The minimum slope for main line conduits shall be .001 (0.10 percent), unless otherwise approved by the governing municipality. The minimum slope requirement is intended primarily to provide some drainage of the system after each storm event and does not eliminate the need to meet the minimum velocity requirement.

4.2.2.4 Hydraulic/Energy Grade Line: Often a closed conduit designed for open channel flow operates as a pressure conduit. This may result when storm runoff exceeds that used for design purposes or simply because junction losses were underestimated or neglected in the design. In storm drain systems, junctions in closed conduits *can* cause major losses in the energy grade line across the junction. If these losses are not included in the hydraulic design, the capacity of the conduit may not be adequate for the design flow.

Even though a conduit may be designed to carry stormwater as open-channel flow, losses at bends and junctions will frequently cause pressure flow to occur for some distance upstream of the "loss" area. Situations may occur in steep terrain where the flow often interchanges between open channel and pressure flows. Because it is not economical to size conduits to avoid pressure flow under all storm runoff and flow conditions, it follows that it is reasonable and even necessary to design the conduits as flowing full. Planned management of stormwater runoff is also easier to achieve if the hydraulic grade line is kept higher than the crown of the conduit. The discharge through a circular pipe flowing full is constant for a given pipe diameter and hydraulic gradient. Once the flowing full discharge is reached in the pipe, no further runoff can be admitted to the pipe network. This phenomenon in the field would be evidenced by runoff passing directly over the catch basin to flow down the street (or overland) until it enters the system elsewhere. Another indication is water standing in sumps (detention ponding) until there is sufficient capacity in the storm drain to admit the ponded water. The designer should size the pipes so that the hydraulic grade line is at or very near 6 inches below the inlet elevation. Doing so provides an "automatic safety valve" that will prevent additional runoff from entering the pipe network and causing unforeseen problems at other locations in the system.

Although not always feasible, the recommended procedure is to design storm drains to flow under pressure. Because designing for pressure flow allows for minimizing the capital expenditure required for a specified level of protection. Whether or not the final design is made with the pipe flowing partially or completely full, the hydraulic grade line must be computed and displayed on a profile drawing of the conduit. When the hydraulic grade line rises above ground level, stormwater can be found shooting out of catch basins or popping manhole covers, which can lead to needless damage and inconvenience to pedestrian and vehicular traffic. Therefore, the hydraulic grade line should be at least 6 inches below the inlet elevation.

4.2.2.5 Materials:

All materials used for a storm drain system must be approved by the governing municipality prior to use.

Table 4.1 lists friction factors for commonly used pipe materials.

4.2.2.6 Sizing:

Storm drain systems shall be designed so that the hydraulic grade line is at least 6 inches below the inlet elevation.

The general procedures for establishing the quantity of flow and layout are the same for a closed conduit flowing either as an open channel or as a pressure conduit. Because of the nature of hydraulic elements in circular conduits, it may be reasonably assumed that open channel flow will occur only when the flow depth is less than 80 percent of the conduit diameter.

The designer should initially size the pipes to carry excess runoff to meet the 10-year street encroachment criteria of Table 3.1. Once this runoff has been admitted to the pipe network, additional runoff can be carried by surcharge in the street to a level of encroachment allowed by Table 3.1 for the 100-year storm. If the encroachment criteria is exceeded for the 100-year storm, then the pipe sizes should be increased to carry the extra runoff.

Minimum Pipe Size: The minimum diameter of a main line conduit should be 24 inches, unless otherwise approved by the governing municipality. The minimum pipe size of a lateral collector pipe should be 15 inches.

4.2.2.7 Manhole Design Considerations: The following considerations are intended for use when junction losses are an important design consideration. They are not intended to be design requirements.

Alignment of Pipes in Manholes: The following discussion applies to the location of pipes within a manhole to achieve maximum efficiency.

For a straight through-flow, pipes should be positioned vertically so that they are between the limits of inverts aligned or crowns aligned. An offset in the plan is allowable provided the projected area of the smaller pipe falls within that of the larger. Aligning the inverts of the pipes is probably the most efficient as the manhole bottom then supports the bottom of the jet issuing from the upstream pipe.

When two inflowing laterals intersect a manhole, the alignment should be quite different. If lateral pipes are aligned opposite one another so the jets may impinge upon each other, the magnitude of the losses can be extremely high. A design figure for

Liner plates	0.005 to 0.01	0.013 to 0.017	100 to 140

directly opposed laterals is shown in Figure 4.1, although this arrangement should be avoided wherever possible.

If the installation of directly opposed inflow laterals is necessary, the installation of a deflector, as shown in Figure 4.1 will result in significantly reduced losses. The research conducted on this type deflector is limited to the ratios of $D_o/D_i = 1.25$. The tests indicate that it would be conservative to assume the coefficient of pressure change at 1.6 for all flow ratios and pipe diameter ratios when no catch basin is considered, and 1.8 when the catch basin flow is more than 10 percent of Q_o .

Lateral inflow pipes should not be located directly opposite; rather, their centerlines should be separated laterally by at least the sum of the two lateral pipe diameters. Studies have shown that head losses are reduced by this as compared to directly opposed laterals, even with deflectors. Insufficient data has been collected to determine the effect of offsetting laterals vertically.

Shaping Inside of Manhole: Jets issuing from the upstream and lateral pipes must be considered when attempting to shape the inside of manholes.

The tests for full flow revealed that very little, if anything, is gained by shaping the bottom of a manhole to conform to the pipe invert. Shaping of the invert may even be detrimental when lateral flows are involved, as the shaping tends to deflect the jet upwards, causing unnecessary head loss. From a practical point of view limited shaping of the invert is necessary in order to handle low flows, and to reduce sedimentation.

Figure 4.1 details several types of deflector devices that have been found efficient in reducing losses at junctions and bends. In all cases, the bottoms are flat, or only slightly rounded, to handle low flows. Numerous other types of deflectors or shaping of the manhole interiors were tested by the University of Missouri. Some of these devices which were found inefficient are shown in Figure 4.2. The fact that several of these inefficient devices would appear to be improvements indicates that special shapings deviating from those in Figure 4.1 should be used with caution, possibly only after model tests.

Entrances: Tests indicate that rounding entrances or the use of pipe socket entrances do not have the effect on reducing losses that might be expected. Once again, the effect of the jet from the upstream pipe must be considered. Specific reductions to the pressure change factors are indicated with each design figure.

4.2.2.8 Catch Basins: Certain specific design procedures are necessary for storm water catch basins on systems flowing full.

The hydraulic grade line must be at least 6 inches below the gutter grade at the catch basin to allow the catch basin to function properly. If there is any possibility of the hydraulic grade being above this level, adjustments should be made to lower the hydraulic grade line or the inlet should be eliminated in that location. The design procedures for catch basins can be found in Section 3.3.

Directly opposed lateral with deflector
(head losses are still excessive with this method, but are significantly less than when no deflector exists.)

NOTE:

Although these modifications look like improvements, studies have proven these designs to be less efficient than the designs in Figure 4.1.

Use caution when deviating from recommended designs.

Figure 4.2
Inefficient Manhole Shaping
(University of Missouri)

4.2.2.9 Debris: In a few areas there may be a high potential for debris which could block the storm drain. In situations like these, the governing municipality should be contacted for determining how best to minimize the impact of the debris on the storm drain system.

4.2.2.10 Transition from Large to Small Conduit: As a general rule, storm drains are designed with sizes increasing in the downstream direction. However, when studies indicate it may be advisable to decrease the size of a downstream section, the conduit may be decreased in size in accordance with the following limitations:

- a. For slopes of .0025 (0.25 percent) or less, only conduits 78 inches and greater may be decreased in size a maximum of 6 inches.
- b. For slopes of more than .0025, only conduits 36 inches and greater may be decreased in size. Each reduction is limited to a maximum of 3 inches for pipe 48 inches in diameter or smaller, and to a maximum of 6 inches for pipe larger than 48 inches in diameter. Reductions exceeding the above criteria must have approval from appropriate governing municipality.

The reduction in size must include approved transitions, result in a more economical system, and must be shown not to cause any adverse impacts.

4.3 Water Surface Profile Calculations

Presented in this section are the general procedures for hydraulic design and evaluation of storm drains. Calculations to check the pressure (hydraulic grade) of water surface elevations in the storm drain system begin with a known hydraulic grade elevation at some downstream point. To this are added the various losses that occur to determine the upstream hydraulic grade elevation. These losses are commonly referred to as minor losses or head losses. The procedures for calculating the various head losses are presented in Section 4.3.3.

If the hydraulic grade line is above the pipe crown at the upstream junction, full flow calculations may proceed. If the hydraulic grade line is below the pipe crown at the upstream junction, then open channel flow calculations must be used.

To expedite computations, the storm drain hydraulic grade line elevation determined at a junction should first be compared to the elevation of the top of the downstream pipe and the gutter. Because of the usual losses that occur at a junction, the upstream hydraulic elevations and the water elevation in the catch basin are generally higher than the elevation of the downstream storm drain hydraulic grade line. Comparison to limiting conditions will indicate whether the design may or may not be applicable at the junctions.

In this presentation of design methods, provision is made to identify pipes by use of numbered subscripts. The number one (1) is used to identify the upstream main pipe, the number two (2) is used to identify the downstream main pipe, and the number three (3) is used for incoming or branching flow.

4.3.1 Determination of Controlling Water Surface Elevation

A storm drain designed for pressure conditions may discharge into one of the following:

- a. A body of water such as a retention basin, reservoir, or lake.
- b. A natural watercourse or an open channel (either improved or unimproved).
- c. Another closed conduit.

The controlling water surface elevation at the point of discharge is commonly referred to as the control and, for pressure flow, is generally located at the downstream end of the conduit. If flow becomes unsealed, the control may be at the first gradebreak upstream of the point where unsealing occurs or, under certain conditions, may be farther upstream.

The hydraulic grade line elevation for the receiving facility that coincides with the peak flow from the storm drain must be determined. In general the two types of controls are possible for a conduit on a mild slope are:

1. Control elevation above the soffit elevation. In such situations the control shall conform to the following criteria:
 - a. In the case of a conduit discharging into a retention basin the control shall be the retention basin water surface elevation coinciding with the peak flow from the conduit.
 - b. In the case of a conduit discharging into an open channel, the control shall be the water surface elevation of the channel coinciding with the peak flow from the conduit.
 - c. In the case of a conduit discharging into another conduit, the control shall be the highest hydraulic grade line elevation of the outlet conduit immediately upstream or downstream of the confluence.
2. Control elevation at or below the soffit elevation. The control shall be the soffit elevation at the point of discharge. This condition may occur in any one of the situations described earlier.

4.3.2 Instructions for Hydraulic Calculations

Most procedures for calculating hydraulic grade line profiles are based on the Bernoulli equation and can be expressed as:

$$\frac{V_1^2}{2g} + Y_1 + S_o L = \frac{V_2^2}{2g} + Y_2 + S_f L + h_{minor} \quad (4.1)$$

The various terms used in equation 4.1 are identified in Figure 4.3. Minor losses have been included in the Bernoulli equation because of their importance in calculating hydraulic grade line profiles.

The general procedure for the hydraulic calculations is to establish the downstream control elevation. From there the hydraulic calculations proceed upstream from point of interest to point of interest. For example, from one junction to another junction or from a junction to the beginning of a bend. At the lower end of each point of interest the pipe friction losses from the downstream section are added to the downstream hydraulic grade line. The losses through the point of interest are added at the upstream end of the point of interest. The procedures for calculating the various losses encountered in a storm drain system are presented in Section 4.3.3. Figure 4.4 may be used to assist in the accounting and computing of the losses. As depicted, Y_1 and Y_2 include the pressure components since they are above the soffit.

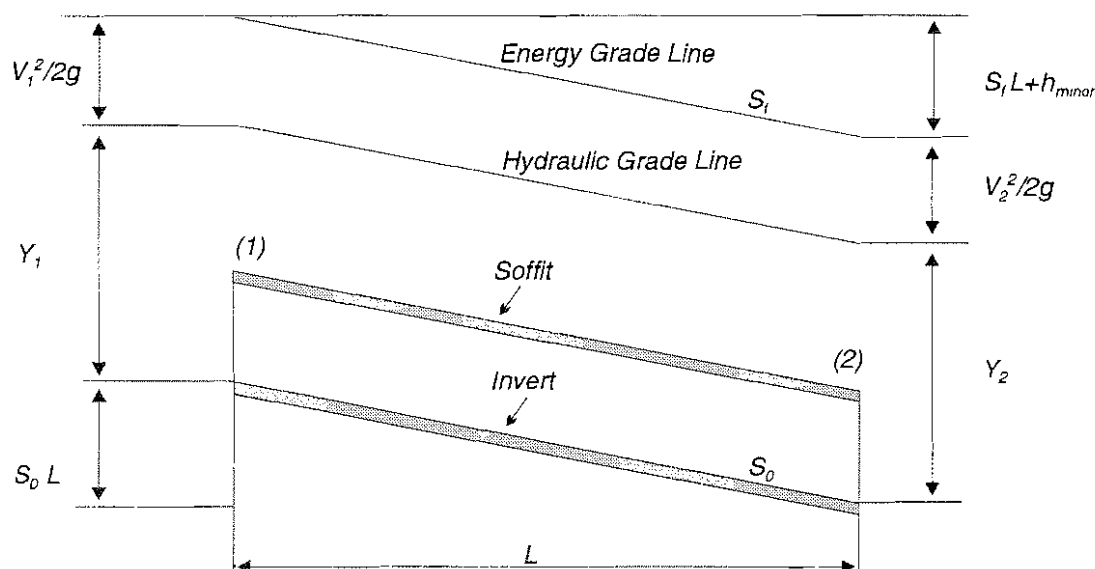

Figure 4.3
Definition of Terms Used in Storm Drain Hydraulic Calculations
 (Los Angeles County Flood Control District, 1982)

Figure 4.4
Hydraulic Grade Line Calculation Sheet

[illegible]

n - Manning's roughness coefficient

Q - rate of flow, ft³/s

V - velocity, ft/s

 $V^2/2g$ - velocity head, ft

$$K = \frac{2gn^2}{2.21}$$

S_f - friction slope, ft/ft

h_f - head loss due to friction, ft

h_b - head loss due to a bend, ft

h_j - head loss due to a junction, ft

h_t - head loss due to a transition, ft

Equation 4.2 is a simplification of a more complex equation and is a convenient method for locating the approximate point where pressure flow may become unsealed is derived by substituting specific energy (E) for the quantity $V^2/2g + Y$ in Equation 4.1 and rearranging the results. For S_f use the average friction slope between the two points of interest.

$$L = \frac{E_2 - E_1}{S_o - S_f} \quad (4.2)$$

4.3.3 Head Losses

The head losses that need to be determined are: friction, transition, junction, manhole, and bend. These losses need to be determined individually and then added together to determine the overall head loss for each segment of the storm drain. The methods for determining the various head losses presented in this section were selected for their wide acceptance and ease of use.

4.3.3.1 Friction Loss: Friction losses for closed conduits carrying storm water, including pump station discharge lines, will be calculated from Manning's equation or a derivation thereof. The Manning's equation is commonly expressed as follows:

$$Q = \frac{1.486}{n} A R^{2/3} S_f^{1/2} \quad (4.3)$$

using,

$$K = \frac{2g n^2}{2.21} \quad (4.4)$$

and the continuity equation with $V=Q/A$, the equation for determining the pipe friction slope can be expressed as,

$$S_f = K \frac{V^2}{2g R^{4/3}} \quad (4.5)$$

The value of K is dependent only upon the roughness coefficient (n) for the pipe. The Manning's n values for various pipe materials are given in Table 4.1.

The loss of head due to friction throughout the length of reach (L) is calculated by:

$$h_f = S_f L \quad (4.6)$$

4.3.3.2 Transition Losses: Figure 4.5 shows the two types of transitions that can be encountered. The head loss due to the expansion of flow is expressed as:

$$h_t = k_e \left(\frac{V_1^2}{2g} - \frac{V_2^2}{2g} \right) \quad \text{for } V_1 > V_2 \quad (4.7)$$

The values for the transition coefficient, k_e , for gradual enlargements are given in Table 4.2. For sudden enlargements use Table 4.3.

The head loss due to the contraction of flow is expressed as:

$$h_t = k_c \left(\frac{V_2^2}{2g} - \frac{V_1^2}{2g} \right) \quad \text{for } V_2 > V_1 \quad (4.8)$$

Values for the transition loss coefficient, k_c , for contractions can be found in Table 4.4.

4.3.3.3 Junction and Manhole Losses: A junction occurs where one or more lateral enters the main storm drain, usually at a manhole. Multiple pipes coming together at a junction should flow together smoothly to avoid high head losses. Figure 4.6 shows a typical junction

The head loss due to the junction for a single lateral can be expressed as:

$$(h_j + D_1 - D_2) \frac{(A_1 + A_2)}{2} = \frac{Q_2^2}{A_2 g} - \frac{Q_1^2}{A_1 g} - \frac{Q_3^2}{A_3 g} \cos \theta \quad (4.9a)$$

And for the situation of multiple laterals:

$$(h_j + D_1 - D_2) \frac{(A_1 + A_2)}{2} = \frac{Q_2^2}{A_2 g} - \frac{Q_1^2}{A_1 g} - \frac{Q_3^2 \cos \theta_3}{A_3 g} - \frac{Q_4^2 \cos \theta_4}{A_4 g} \quad (4.9b)$$

Figure 4.6
Junction Loss

Manhole with a Bend: The head loss in a manhole with a bend is determined using equation 4.10. The bend loss coefficient, k_b , can be determined using Figure 4.7.

$$h_{mh} = k_b \frac{V^2}{2g} \quad (4.10)$$

Straight-Through Manhole: In a straight-through manhole where there is no change in pipe size, or rate of flow, the loss can be estimated by:

$$h_{mh} = 0.05 \frac{V^2}{2g} \quad (4.11)$$

4.3.3.4 Bend Loss: For bends that occur outside of a manhole the additional loss due to the bend is calculated using equation 4.12.

$$h_b = k_b \left(\frac{V^2}{2g} \right) \quad (4.12)$$

The value of the bend loss coefficient, k_b , depends upon the angle and sharpness of the bend and can be determined from Figure 4.7 for values of α not exceeding 90 degrees. Where α is the central angle of the bend in degrees.

Bend losses should be included for all closed conduits, those flowing partially full as well as those flowing full.

4.3.4 Computer Programs

There are many computer programs available to help in the design of storm drain systems. These programs may use different methods to determine the various losses than those presented in this chapter. Therefore, the designer of the storm drain system should check with the governing municipality before using a particular program.

4.4 Design Requirements for Maintenance and Access

4.4.1 Manholes

4.4.1.1 Spacing:

Conduit diameter 30 inches or smaller: Manholes shall be spaced at intervals of approximately 300 feet. Where the proposed conduit is less than 30 inches in diameter and the horizontal alignment has numerous bends or angle points, the manhole spacing will be reduced to 200 feet, or less.

Conduit diameter larger than 30 inches but smaller than 48 inches: Manholes shall be spaced at intervals of approximately 400 feet.

Conduit diameter 48 inches or larger: Manholes shall be spaced at intervals of approximately 500 feet.

The spacing requirements shown above apply regardless of design velocities. Deviations from the above criteria shall be subject to approval from the appropriate governing municipality.

Figure 4.7
Bend Loss Coefficient
(University of Missouri, 1958)

4.4.1.2 Location: In situations where the proposed conduit is to be aligned both in easement and in street right of way, manholes should be located in street right of way, wherever possible. Manholes shall not be located in intersections except for access to a junction structure.

Manholes shall be located as close to changes in the grade as feasible when the following conditions exist:

- a. ~~When the upstream conduit has a steeper slope than the downstream~~ conduit and the change in grade is greater than 10 percent, because sediment tends to deposit at the point where the change in grade occurs.
- b. Where a transition to a smaller downstream conduit occurs due to an abruptly steeper slope downstream, since debris tends to accumulate at the point of transition.

4.4.1.3 Design: Manholes shall be designed to minimize head losses as much as possible. For systems flowing full with a velocity of 20 ft/s or greater, or with supercritical flow in a partially full pipe, the total horizontal angle of divergence or convergence between the walls of the manhole and its center line should not exceed 10°.

4.4.1.4 Pressure Manholes: A pressure manhole shaft and a pressure frame and cover shall be installed in a pipe or box storm drain whenever the design water surface is higher than, or within 6 inches of the top of the manhole cover. In cases where the flow in the storm drain could exceed the design Q, and the water surface for the higher Q could produce a water surface above the top of the manhole cover, a pressure manhole shaft and a pressure frame and cover must be installed.

4.4.2 Inlets/Outlets

4.4.2.1 Inlets into Main Line Drains: Lateral pipe entering a main line pipe storm drain generally shall be connected radially. Lateral pipe entering a main line box structure shall conform to the following:

- a. Lateral pipe 24 inches or less in diameter shall be no more than five feet above the invert.
- b. Lateral pipe 27 inches or larger in diameter shall be no more than 18 inches above the invert, with the exception that catch basin connector pipe less than 50 feet in length may be no more than five feet above the invert.

Exceptions to the above requirements may be permitted where it can be shown that the cost of bringing laterals into a main line box conduit in conformance with the above requirements would be excessive.

4.4.2.2 Inlet Structures: In general the interception of flow from a natural watercourse directly into a storm drain system must be avoided. If avoiding this situation isn't possible, then an inlet structure must be provided and strong consideration has to be given to the use of a debris or sediment basin. The inlet structure should generally consist of a headwall, wingwalls to protect the adjacent banks from erosion, and a paved inlet apron. Wall heights should conform to the height of the water upstream of the inlet, and be adequate to protect both the fill over the drain and the embankments. Headwall and wingwall fencing and the District's Standard protection barrier or trash rack must be provided to prevent public entry. The trash rack should be used for inlets 48-inches (diameter or width) and smaller. For inlets larger than 48-inches a special designed trash rack may be required. Section 5.3 provides more details on entrances and outlets for storm drains. See Sections 5.2.2.13 and 6.3.2.4 for more information on safety and fencing.

4.4.2.3 Outlet Structures: When a storm drain outlets into a natural channel, an outlet structure must be provided which prevents erosion and property damage. Velocity of flow at the outlet should agree as closely as possible with the existing channel velocity. Fencing and a protection barrier should be provided.

- a. When the discharge velocity is low, or subcritical, the outlet structure shall consist of a headwall, wingwalls, and an apron. The apron may consist of a concrete slab, or grouted rock.
- b. When the discharge velocity is high, or supercritical, the designer shall, in addition, consider bank protection in the vicinity of the outlet and an energy dissipator structure.

Sections 5.3 and 7.4 have more information on entrances and outlets for storm drains.

4.4.2.4 Protection Barriers and Trash Racks: A protection barrier is a means of preventing people and animals from entering storm drains. Protection barriers may consist of large, heavy breakaway gates, single horizontal bars across catch basin openings, or chain link fencing around an inlet or an exposed outlet. See section 5.2.2.11 for more information on trash racks.

4.5 Rational Method for Sizing Storm Drain Systems

This section provides a method of estimating the flows needed to size a storm drain system using the Rational Equation, $Q = CIA$, as it is defined in Volume I of the *Drainage Design Manual* (see also steps 8 through 11). The time of concentration (T_c), for the storm drain system at the location of each catch basin must be calculated a minimum of two ways. The time of concentration for the above ground portion of flow must be determined, as well as the time of concentration for flow through the storm drain system. *It should be stressed that the Rational Method was originally developed*

to estimate runoff from small areas and that the peak generated by the Rational Method cannot be hydrologically routed.

The designer should proceed with the final hydraulic design of the system only after:

- The preliminary minor system design is completed and checked for its interaction with the major runoff;
- ~~Reviews are made of alternatives;~~
- Hydrological assumptions are verified; and
- Final data is obtained on street grades, elevations, and potentially conflicting utilities.

The following paragraphs provide an outline of the *Storm Drain System - Preliminary Design Data Form*, Figure 4.8, which was created to help the designer estimate flows for storm drain sizing. This form is for the average situation and variations will often be necessary to fit actual field conditions.

1. ***Location of Design Point:*** Determine design point location and list. This design point should correspond to the subbasin illustrated on the preliminary layout map.
2. ***Basins:*** List basins contributing runoff to this point which have not previously been analyzed.
3. ***Length, ft:*** Enter length of flow path between previous design point and design point under consideration.
4. ***Inlet Time, minutes:*** Determine the inlet time in minutes for the particular design point. For the first design point on a system, the inlet time will be equal to the time of concentration. For subsequent design points, inlet time should also be tabulated to determine if it may be of longer duration than the accumulated time of concentration from upstream basins. If the inlet time exceeds the time of concentration from the upstream basin, and the area tributary to the inlet is of sufficient magnitude, the longer inlet time should be substituted for time of concentration and used for this and subsequent basins.
5. ***Street Flow Time, minutes:*** Enter the appropriate flow time between the previous design point and the design point under consideration. The flow time of the street should be used if a significant portion of the flow from the above basin is carried in the street.
6. ***Pipe Flow Time, minutes:*** Pipe flow time should generally be used unless there is significant carry-over from the above basins in the street (column 3/(column 22)(60)).

7. **Time of Concentration, minutes:** The time of concentration is either for the above ground portion of flow to the inlet time, or the summation of the previous design point's time of concentration and the intervening flow time, whichever produces the greater peak discharge.
8. **Coefficient "C":** Rational Method Runoff Coefficient, "C," from the *Drainage Design Manual for Maricopa County, Volume I, Hydrology* (FCD 1992, Table 3.2), for the basins listed in Column 2 should be determined and listed. The "C" value should be weighted if the basins contain areas with different "C" values.
9. **Intensity "I," inches/hour:** The intensity to be applied to the basins is obtained from the time-intensity-frequency curve developed for the specific area based upon the depth-duration-frequency curves in *Drainage Design Manual for Maricopa County Volume I, Hydrology*. The intensity is determined from the time of concentration as described in item number 7, and the design frequency for this particular design point.
10. **Area, "A," acre:** The area of the basins (in acres) listed in Column 2 is tabulated here. Subtract ponding areas which do not contribute to direct runoff such as rooftop and parking lot ponding areas.
11. **Direct Runoff "Q," cfs:** Direct runoff from the tributary basins listed in Column 2 is calculated and tabulated here by multiplying Columns 8, 9, and 10 together.
12. **Other Runoff, cfs:** Runoff from other sources, such as controlled releases from rooftops, parking lots, base flows from groundwater, and any other source, is listed here. List the bypass discharge, if any, with a "-" in front.
13. **Summation Runoff, cfs:** The total of runoff from the previous design point summation plus the incremental runoff listed in Columns 11 and 12 is listed here.
14. **Street Slope, percent:** The proposed street slope is listed in this column.
15. **Street Allowable Capacity, cfs:** The allowable capacity for the street is listed in this column. Allowable capacities should be calculated in accordance with procedures set forth in Section 3.2.
16. **Pipe Slope, percent:** List the proposed pipe grade.
17. **Pipe Size, inches:** List the required pipe size to convey the quantity of flow necessary in the pipe.
18. **Pipe Capacity, cfs:** List the capacity of the pipe flowing full with the slope

expressed in Column 16.

19. **Street Design, cfs:** Tabulate the quantity of flow to be carried in the street.
20. **Street Velocity, fps:** List the actual velocity of flow for the volume of runoff to be carried in the street.
21. **Pipe Design, cfs:** List the quantity of flow determined to be carried in the pipe.
22. **Pipe Velocity, fps:** Tabulate the actual velocity of flow in the pipe for design.
23. **Remarks:** Include any remarks or comments which may affect or explain the design. The allowable quantity of carry-over across the street intersections should often be listed for the minor design storm. When routing the major storm through the system, required elevations for adjacent buildings can often be listed in this column.

Culverts and Bridges

5.1 Definition of Symbols

The following symbols will be used in equations throughout Chapter 5.

θ_g	=	Angle of bar grate with respect to the horizontal, degrees
θ_j	=	Angle between outfall and lateral at a junction, degrees
ρ	=	Density of fluid
τ_c	=	Critical tractive shear stress, lb/ft ²
a	=	Angle of approach, degrees
A	=	Area of the barrel, ft ²
C_i	=	Embankment overtopping discharge coefficient
d_c	=	Critical depth, ft
d_{50}	=	Diameter of a rock particle for which 50% of the gradation is finer by weight (other percentages may also be used)
D	=	Pipe culvert diameter or box culvert depth, ft
$D.I.$	=	Discharge intensity
EL_o	=	Invert elevation at the outlet, ft
EL_{ho}	=	Outlet control headwater elevation, ft
F_r	=	Froude number
g	=	Acceleration due to gravity, 32.2 ft/s ²
H	=	Sum of inlet loss, friction loss, and velocity head in a culvert, ft
H_b	=	Head loss through a bend of a culvert, ft
H_g	=	Head loss through a trash rack, ft
H_j	=	Head loss through a junction, ft
H_l	=	Head loss due to turning flow at a headwall, ft
H_v	=	Velocity head, ft
HW	=	Depth from inlet invert to upstream total energy grade line, ft
HW_r	=	Flow depth above the roadway, ft
h_o	=	Height of hydraulic grade line above outlet invert, ft
h_s	=	Depth of scour, ft
h_t	=	Height of tailwater above crown of submerged road, ft
K_b	=	Bend loss coefficient

K_e	=	Entrance loss coefficient
K_g	=	Dimensionless bar shape factor
K_t	=	Submergence factor
L	=	Actual length of culvert, ft
L_l	=	Adjusted culvert length, ft
L_a	=	Length of apron, ft
L_r	=	Length of roadway crest along the roadway, ft
L_s	=	Length of scour, ft
L_{SB}	=	Length of scour basin, ft
L_x	=	Length of overflow sections along embankment, ft
n	=	Manning's n value
n_1	=	Desired Manning's n value
PI	=	Plasticity index
Q	=	Rate of flow, cfs
Q_o	=	Rate of flow overtopping roadway, cfs
Sn_{mod}	=	Modified shear number ($\rho V^2/\tau_c$)
S_v	=	Saturated shear strength, lb/in ²
TW	=	Tailwater depth measured from culvert outlet invert, ft
t	=	Time in minutes
t_o	=	Base time used in experiments to derive scour coefficients α , β , and θ , use 316 minutes unless specified otherwise
V	=	Velocity, ft/s
V_a	=	Approach velocity, ft/s
V_g	=	Velocity between the bars of a trash rack, ft/s
V_s	=	Volume of scour, ft
W_a	=	Width of apron, ft
W_s	=	Width of scour, ft
w	=	Maximum cross-sectional width of the bars facing the flow, ft
x	=	Minimum clear spacing between bars, ft
y'	=	Change in hydraulic grade line through the junction, ft
y_e	=	Equivalent depth, ft
y_s	=	Depth of scour, ft

5.2 Culverts

The charts and procedures for culvert design used in this manual are taken from the Federal Highway Administration Hydraulic Design Series Number 5, *Hydraulic Design of Highway Culverts*. Culvert designers use this reference liberally as it is the result of years of research and experience in culvert design and at this time represents the state of the art.

5.2.1 Interaction of Culverts with Other Systems

Culverts are primarily used for conveying runoff through a roadway embankment. They are normally aligned with a natural wash or drainage channel, which are often outfalls for storm drainage systems. Culverts are typically associated with drains on such a scale where bridges are not feasible. Regional drains are generally of a magnitude that justifies the use of bridges.

5.2.2 Culvert Design Criteria

5.2.2.1 Sizing:

Culverts for collector and arterial streets are to be designed to convey at least the 50-year peak discharge with no flow crossing over the roadway.

5.2.2.2 Minimum Velocity: A minimum velocity of 3.0 feet per second at design capacity is recommended to assure a self-cleaning condition during partial depth flow.

5.2.2.3 Maximum Velocity: As a practical limit, outlet velocities should be kept below 15 feet per second unless special conditions exist. The maximum velocity should be consistent with channel stability requirements at the culvert outlet. As outlet velocities increase, the need for channel stabilization at the culvert outlet increases. If culvert outlet velocities exceed permissible velocities for the outlet channel lining material, suitable outlet protection must be provided. Outlet velocities may exceed permissible downstream channel velocities by up to 10 percent without providing outlet protection if the culvert tailwater depth is greater than the culvert critical depth of flow under design flow conditions. Tables 6.1, 6.2 and 6.3 (pages 6-11, 6-12, and 6-15) outline the permissible velocities for several channel lining materials.

5.2.2.4 Materials: The selection of a culvert material may depend upon structural strength, hydraulic roughness, durability, and corrosion and abrasion resistance. The three most common culvert materials are concrete (reinforced and nonreinforced), corrugated aluminum, and corrugated steel. Culverts may also be lined with other materials to inhibit corrosion and abrasion. Linings are not recommended to reduce hydraulic resistance because culvert linings have a short life span and are seldom reapplied as part of normal culvert maintenance. When linings are applied, the culvert sizing should neglect the reduced roughness from the lining material.

5.2.2.5 Minimum Cover: Minimum cover of fill over culverts must be provided to maintain the structural integrity of the pipe under anticipated loading conditions. Culvert manufacturers provide minimum cover requirements for prefabricated pipe. A rule of thumb for estimating minimum cover requirements is to provide one-eighth of the barrel diameter or span, with a minimum of 1 foot. The top of culverts should not extend into

the roadway subgrade. Minimum cover should be measured from the top of subgrade which is the bottom of the pavement structural section.

5.2.2.6 Depth for Road Crossing:

Culverts for collector and arterial streets are to be designed to convey at least the 50-year peak discharge with no flow crossing over the roadway. Additionally, the flow depth over the roadway shall be limited to 0.5 feet for the 100-year peak discharge.

Regardless of the size of the culvert, street crossings shall be designed to convey the 100-year storm runoff under and/or over the road to an area downstream of the crossing to which the flow would have gone in the absence of the street crossing. Flows up to and including the 100-year frequency event should not cause increased flooding to adjacent property or buildings, unless a drainage easement is acquired for those areas. The ponded headwater elevation should be delineated on a contour map, or other surveying methods used to identify the area inundated by the ponded water.

In general, dip sections are not allowed. However, for flows crossing broad shallow washes where the construction of a culvert is not practical or desirable, the road may be dipped to allow the entire flow to cross the road. Use of dip sections must be approved by the governing municipality. The pavement through the dip section should have a one way slope parallel to flow and curbs and medians must not be raised. Upstream and downstream cutoff walls and aprons should be provided to minimize headcutting and erosion.

5.2.2.7 Scour and Sedimentation:

Possible aggradation or degradation at culvert crossings must be examined in the design of culverts.

An adequate system of culvert design involves passing drainage water and sediment from the upstream regime condition of the channel crossing without upsetting the delicate balance between hydraulics and sediment transport flow.

The effects of scour and deposition should be minimized by protecting the outlet from scour with suitable outlet protection measures and reducing sedimentation problems by avoiding inlets depressed below the natural channel flowline and multi-barrel installations that reduce the channel velocity for low flows. Culverts which are located on and aligned with the natural channel are less susceptible to sedimentation problems.

5.2.2.8 Skewed Channels: A good culvert design is one that limits the hydraulic and environmental stress placed on the existing natural water course. This stress can be minimized by designing a culvert which closely conforms to the natural stream in alignment, grade, and width.

Often the culvert barrel must be skewed with respect to the roadway centerline to accomplish these goals. Alterations to the normal inlet alignment are also quite common.

The alignment of a culvert barrel with respect to a line normal to the roadway centerline is referred to as the barrel skew angle. A culvert aligned normal to the roadway centerline has a zero barrel skew angle. Directions (right or left) must accompany the barrel skew angle (Figure 5.1).

The barrel skew is established from the stream location and the proposed or existing roadway plan. The advantages of using a natural stream alignment include a reduction of entrance losses, equal depths of scour at the footings, less sedimentation in multibarrel culverts, and less excavation. The disadvantage of this design procedure is that the inlet may be skewed with respect to the culvert barrel and the culvert will be longer, sometimes resulting in increased initial costs.

The angle from the culvert face to a line normal to the culvert barrel is referred to as the inlet skew angle (Figure 5.2). The structural integrity of circular sections is compromised when the inlet is skewed due to loss of a portion of the full circular section where a portion of the culvert barrel extends beyond the full section. Although concrete headwalls help stabilize the pipe section, structural considerations should not be overlooked in the design of skewed inlets.

Culverts which have a barrel skew angle often have an inlet skew angle as well. This is because headwalls are generally constructed parallel to a roadway centerline to avoid warping of the embankment fill.

Figure 5.1
Barrel Skew Angle
 (USDOT, FHWA, HDS-5, 1985)

Figure 5.2
Inlet Skew Angle
 (USDOT, FHWA, HDS-5, 1985)

In cases where the culvert barrel cannot be aligned with the channel flowline, such as when runoff is directed parallel to the roadway embankment to a suitable crossing location, the flow enters the culvert barrel at an angle. The approach angle should be limited to a maximum of 90 degrees. When high velocities exist, inlet losses resulting from turning the flow into the culvert should be considered. If backwater computations are not employed and the approach channel velocity is 6 feet per second or greater, the following equation should be used to estimate the loss. The loss should be added to the other inlet losses in the culvert design computation, if they aren't included in the appropriate nomographs.

$$H_i = \left(\frac{V_a^2}{2g} \right) \sin a \quad (5.1)$$

Typical headwall/wingwall configurations for skewed channels are shown in Figure 5.3.

5.2.2.9 Bends: A straight culvert alignment is desirable to avoid clogging, increased construction costs, and reduced hydraulic efficiency. However, site conditions may dictate a change of alignment, either in plan or in profile. When considering a nonlinear

FLOW NORMAL TO EMBANKMENT

FLOW PARALLEL TO EMBANKMENT

FLOW SKEWED TO EMBANKMENT

FLOW AND CULVERT SKEWED TO EMBANKMENT

Figure 5.3
Typical Headwall/Wingwall Configurations

Figure 5.4
"Broken Back" Culvert
 (USDOT, FHWA, HDS-5, 1985)

culvert alignment, particular attention should be given to erosion, sedimentation, and debris control. Vertical bends are permitted when they transition from a flatter to a steeper slope, but should not transition from steeper to flatter slopes because of the potential for sediment deposition in the flatter reach.

In designing a nonlinear culvert, the energy losses due to the bends must be considered. If the culvert operates in inlet control, no increase in headwater occurs unless the bend losses cause the culvert to flow under outlet control. If the culvert operates in outlet control, an increase in energy losses and headwater will result due to the bend losses. To minimize these losses, the culvert should be curved or have bends not exceeding 15 degrees at intervals of not less than 50 feet. Under these conditions, bend losses can be ignored.

If these conditions cannot be met, analysis of bend losses is required. Bend losses are a function of the velocity head in the culvert barrel. To calculate bend losses, use the following equation:

$$H_b = K_b \frac{V^2}{2g} \quad (5.2)$$

H_b is added to the other outlet losses. Figure 4.6 (page 4-17) can be used to determine loss coefficients (K_b) for bend losses in conduits flowing full.

The broken back culvert, shown in Figure 5.4, has four possible control sections: the inlet, the outlet, and the two bends.

The upstream bend may act as a control section, with the flow passing through critical depth just upstream of the bend. In this case, the upstream section of the culvert operates in outlet control and the downstream section operates in inlet control. Outlet control calculation procedures can be applied to the upstream barrel, assuming critical depth at the bend, to obtain a headwater elevation. This elevation is then compared with the inlet and outlet control headwater elevations for the overall culvert. The controlling flow condition produces the highest headwater elevation. Control at the lower bend is very unlikely and that possible control section can be ignored except for the bend losses in outlet control.

5.2.2.10 Junctions: Flow from two or more separate culverts or storm sewers may be combined at a junction into a single culvert barrel. For example, a tributary and a main stream intersecting at a roadway crossing can be accommodated by a culvert junction (Figure 5.5).

Loss of head may be important in the hydraulic design of a culvert containing a junction. Attention should be given to streamlining the junction to minimize turbulence and head loss. Also, timing of peak flows from the two branches should be considered in analyzing flow conditions and control. When possible, the tributary flow should be released downstream of the culvert barrel. When this is not practical, the following procedure should be used to estimate the losses.

For a culvert barrel operating in outlet control and flowing full, the junction loss is calculated using the equations given below. The loss is then added to the other outlet control losses.

$$H_j = y' + H_{v1} - H_{v2} \quad (5.3)$$

Figure 5.5
Culvert Junction
(USDOT, FHWA, HDS-5, 1985)

The formula for y' is based on momentum considerations and is as follows:

$$y' = \frac{Q_2 V_2 - Q_1 V_1 - Q_3 V_3 \cos \theta_j}{0.5(A_1 + A_2)g} \quad (5.4)$$

The subscripts 1, 2, and 3 refer to the outlet pipe, the upstream pipe, and the lateral pipe respectively.

5.2.2.11: Trash Racks: For trash racks with approach velocities less than 3 fps, it is not necessary to include a loss for the trash rack; however, for velocities greater than 3 fps, such computations are required.

Trash racks can promote debris buildup and the subsequent reduction of hydraulic performance. Thorough analysis of this potential should be undertaken prior to their use. Depending on the anticipated volume and size of the debris an open area between the bars of 1.5 to 3.0 times the area of the culvert entrance should be provided.

$$H_g = 1.5 \frac{[V_g^2 - V_a^2]}{2g} \quad (5.5)$$

Trash rack losses are a function of velocity, bar thickness, bar spacing, and orientation of the flow entering the rack, the latter condition being an important factor. Trash racks with bars oriented horizontally are not permitted, and horizontal bars used to support vertically oriented bars should be as small as practical and kept to the minimum required to meet structural requirements.

The expected loss from a trash rack is greatly affected by the approach angle. The loss computed by Equation 5.5 should be multiplied by the appropriate value from Table 5.1, when the approach channel and culvert are at an angle to each other.

Table 5.1
Loss Factors for Approach Angle Skewed to Entrance

Approach Angle, degrees	Loss Factor
0	1.0
20	1.7
40	3.0
60	6.0

5.2.2.12 Flotation and Anchorage: Flotation is the term used to describe the failure of a culvert due to the uplift forces caused by buoyancy. The buoyant force is produced from a combination of high head on the outside of the inlet and the large region of low pressure on the inside of the inlet caused by flow separation. As a result, a large bending moment is exerted on the end of the culvert. This problem has been noted in the case of culverts under high head, with shallow cover, on steep slopes, and with projecting inlets. The phenomenon can also be caused by debris blocking the culvert end or by damage to the inlet. The resulting uplift may cause the inlet ends of the barrel to rise and bend. Occasionally, the uplift force is great enough to dislodge the embankment. Generally, flexible barrel materials are more vulnerable to failure of this type because of their light weight and lack of resistance to longitudinal bending. Large, projecting, or mitered corrugated metal culverts are the most susceptible.

A number of precautions can be taken by the designer to guard against flotation. Steep slopes (1 to 1 or steeper) of adequate height, which are protected against erosion by slope paving or head walls, help inlet and outlet stability. When embankment fill heights are less than 1.5 times the pipe diameter or fill slopes are flatter than 1 to 1, flexible pipe installations should be provided with concrete headwalls for dead load, and rigid pipe installations susceptible to separation at the joints should be protected with tie bars. Limiting headwater buildup also helps prevent flotation. It is desirable to limit design headwater depths to 1.5 times the culvert height.

5.2.2.13 Safety: The issue of safety includes the following principals:

1. Stormwater naturally accumulates, frequently in amounts that present hazards to property, traffic, and life and health.
2. Because of the accumulation of stormwater, certain levels of hazards cannot be eliminated.
3. Stormwater frequently carries substantial amounts of debris that can threaten the hydraulic capacity of drainage facilities.
4. Devices placed on drainage facilities to restrict access by pedestrians will also restrict hydraulic capacity.
5. Multipurpose uses of many conduits are desirable, may provide safer day to day conditions, and require relatively easy pedestrian access to drainage works in order to be effectively used (trash racks would preclude this use).

During design, culvert entrances may require additional consideration for safety and for debris transported by stormwaters. Frequently, trash collection devices are also used as safety devices. The need for trash collection or safety devices should be determined during planning and before the design of drainage facilities. It is rare that cost-effective trash collectors can be retroactively added without a reduction of intended system design capacity. In any case, it is not a good policy for a failure of protection devices for

humans to result in more property damage or greater hazards to traffic than would have happened if the protection devices were not used.

Safety devices can be divided into two types (U.S. Bureau of Reclamation):

Category I - Devices that Limit or Deter Access

- Fencing
- Guard rails
- Warning signs
- Pipe safety barriers

Category II - Devices that Permit Escape

- Safety nets
- Safety cables
- Safety racks
- Safety ladders

An important distinction between these two categories is that Category II, Safety Devices, may also impede the flow of stormwater into or through drainage facilities. There are three categories of safety to consider:

1. Life and Health
2. Traffic
3. Property

Primary safety issues are life and health safety; however, protection of traffic and property are also concerns. Life and health hazards are classified according to Table 5.2.

From Table 5.2, all of the Phoenix Metropolitan Area would be categorized by classes A, B, or C. Considering growth potential, there are probably few areas of the county that a classification of less than class B should be considered. Safety for drainage facilities should be considered for both dry weather and runoff conditions. Dry weather hazards include traffic and personal safety. Examples of traffic hazards include: improper placement of guard rails on structures; unprotected drops at structures located near roads; and grading which promotes vehicle rollovers.

Table 5.2
Classification of Hazard Exposures
 (U.S. Bureau of Reclamation)

Hazard Class	Nearby Activities
A	Waterways adjacent to schools and recreational areas, such as playgrounds, subject to frequent visits by children.
B	Waterways nearby or adjacent to urban areas or highways and subject to frequent visits by the public.
C	Waterways nearby or adjacent to farms or highways which could be subject to visits by children seeking recreation.
D	Waterways far removed from any dwelling, subject to infrequent visits by operating personnel and an occasional sportsmen.
E	Waterways that would be a hazard to domesticated animals.
F	Waterways that would be an extreme hazard to big game animals.

During large storm events, people will sometimes walk or play in water that can carry them to drainage structures which are dangerous during flood conditions. Or, worse, purposely boat or float in drainage facilities during high runoff levels with the same results. It is not possible to develop drainage facilities that are totally safe, that will preclude people from doing unintelligent acts, and that will also be hydraulically efficient. These objectives are, for the most part, mutually exclusive. However, reasonable levels of protection can be provided to people exercising reasonable judgement even when the structure is performing its primary function, i.e., efficiently passing storm water.

The basic concept of this proposed approach to safety is to apply more restrictive measures as hazards increase. The primary purpose for constructing drainage facilities is the efficient conveyance of stormwater to minimize property damage and to permit traffic flow across and parallel to drainages; therefore, safety in this context will refer to protection from life and health hazards.

When any of the following conditions are met, trash racks will be required on the entrances to all conduits in areas of Class A or B hazard as determined from Table 5.2:

- » When a conduit outfalls into a channel with side slopes steeper than 4(H):1(V) for concrete, grass and earth linings, and 3(H):1(V) for riprap linings.
- » Conduits smaller than 7 feet in diameter, longer than 100 feet in length, or without 12-inches of freeboard at the design flow rate.
- » Conduits with energy dissipators at the end.
- » Conduits being used as outlets from multiple-use detention facilities.
- » Conduits with sufficient bend that the opposite end cannot be clearly seen.

A plugging factor of 50 percent will be used on all trash racks.

Conditions that will cause trash racks to be used on outlets include:

1. Storm sewers, and
2. Pipes smaller than 7 feet in diameter that flow into recreation areas that are not designed for pedestrian use.

Flap gates can be considered for substitution for trash racks on conduit outlets when it can be shown that sedimentation will not prevent the flap gate from opening or that the design of the outlet structure will reduce downstream sedimentation that would prevent the flap gate from opening.

In instances where open channels connect conduits that meet the geometric and hazard requirements previously listed, Category I safety devices are required to restrict access to the general public along the entire reach of that channel. An example is a concrete lined channel with 1:1 side slopes in a Class B hazard, where the channel connects to culverts and the lower culvert has an energy dissipator at its outlet.

Some additional conditions to consider are:

- New development must meet predetermined standards that control flooding. Design for safety should not compromise those standards.

- Drainage works in existing areas will often not meet the standards for flooding that is required of new development; however, where possible, the generally agreed level of protection against flooding should be attained without compromise for life and health safety.

5.2.2.14 Inlets: Culvert inlets are used to transition the flow from a ponded condition upstream of the culvert into the culvert barrel. Losses caused by the inlets have been studied extensively for several types of inlets. The inlet control nomographs in Section 5.2.4 give the required headwater depth to pass the design discharge through several types of culvert entrances. The hydraulic capacity of a culvert may be improved by appropriate inlet selection. Since the natural channel is usually wider than the culvert barrel, the culvert inlet edge represents a flow contraction and may be the primary flow control. The provision of a more gradual flow transition will lessen the energy loss and thus create a more hydraulically efficient inlet condition. Design charts for improved inlets are contained in *Hydraulic Design of Highway Culverts* (USDOT, FHWA, HDS No. 5, September 1985). It should be noted that improving culvert inlets will cause the greatest increase in culvert capacity when the culvert is operating in inlet control.

The hydraulic performance of culverts operating in inlet control can be improved by changing the inlet geometry of the headwall. Improvements include bevel-edged, side-tapered, and slope-tapered inlets. The advantage of these improvements is to convert an inlet control culvert closer to outlet control by using more of the barrel capacity.

A beveled-edge provides a decrease in flow contraction losses at the inlet and the entrance loss coefficient, K_e , is reduced from 0.5 to 0.2, which can increase the culvert capacity by as much as 20 percent. Bevels are required on all culverts with headwalls and should be constructed as shown in Figure 5.6.

Side-tapered inlets have an enlarged face area accomplished by tapering sidewalls as shown on Figure 5.7. It provides an increase in flow capacity of 25 to 40 percent over square-edged inlets. There are two types of control sections for side-tapered inlets: face and throat control. The advantages of side-tapered inlet under throat control are: reduced flow contraction at the throat and increased head at the throat control section.

Slope-tapered inlets provide additional head at the throat section as shown on Figure 5.8. This type of inlet can have over 100 percent greater capacity than a conventional culvert with square edges. The degree of increased capacity depends upon the drop between the face and the throat section. Both the face and the throat are possible control sections. The inlet face should be designed with a greater capacity than the throat to insure flow control at the throat. More of the potential capacity of the culvert can then be insured.

The inlet control nomographs contained in Section 5.2.4 do not apply to the condition when drop inlets are used with or without grates. The turbulence caused by the flow dripping into the inlet box causes additional losses that are not accounted for in the inlet nomographs. The use of drop inlets is discouraged in culvert applications because of the

(USDOT, FHWA, HDS-5, 1985)

danger of plugging from sediment and plugging of grated inlets from debris.

Prefabricated steel inlet end sections (Figure 5.9) are available for corrugated steel pipe that perform about as well as a square-edged headwall inlet with an entrance loss coefficient of 0.5.

When there is a potential for inlet uplift failure or inlet damage from other sources, concrete headwalls are required on culvert installations unless it can be shown that these dangers do not exist.

In some cases metal end sections such as the one shown in Figure 5.9 may be allowed.

Figure 5.9
Prefabricated Culvert End Section

5.2.2.15 Outlets: The receiving channel at culvert outlets must be protected from the high culvert outlet velocities caused by the flow constriction that is inherent in culvert operation. If the culvert outlet velocity is greater than the allowable velocity for the receiving channel lining material, protective measures must be provided.

Projecting culvert outlets are not permitted unless approved by the appropriate governing agency.

The minimum requirement is to provide a preformed metal or concrete end section or a headwall with or without a wingwall configuration with a cutoff wall provided at the end of the apron. Culvert outlet designs are presented in Section 5.3. Energy dissipation structures are presented in Chapter 7.

5.2.3 Design Procedures

5.2.3.1 Culvert Design Method: This design method provides a convenient and organized procedure for designing culverts, considering inlet and outlet control. While it is possible to follow the design method without an understanding of culvert hydraulics, this is not recommended.

The first step in the design process is to summarize all known data for the culvert at the top of the Culvert Design Form (Figure 5.10). This information will have been collected or calculated prior to performing the actual culvert design. The next step is to select a preliminary culvert material, shape, size and entrance type. The user then enters the design flow rate and proceeds with the inlet control calculations.

Inlet Control: The inlet control calculations determine the headwater elevation required to pass the design flow through the selected culvert configuration if the culvert is operating in inlet control. The inlet control nomographs of Section 5.2.4. are used in the design process. For the following discussion, refer to the schematic inlet control nomograph shown in Figure 5.11.

1. Locate the selected culvert size (point 1) and flow rate (point 2) on the appropriate scales of the inlet control nomograph. (Note that for box culverts, the flow rate per foot of barrel width is used.)
2. Using a straightedge, extend a straight line from the culvert size (point 1) through the flow rate (point 2) and mark a point on the first headwater/culvert height (HW/D) scale (point 3). The first HW/D scale is also a turning line.
3. If another HW/D scale is required, extend a horizontal line from the first HW/D scale (the turning line) to the desired scale and read the result.

Figure 5.11
Inlet Control Nomograph (Schematic)
(USDOT, FHWA, HDS-5, 1985)

4. Multiply HW/D by the culvert height, D , to obtain the required headwater (HW) from the invert of the control section to the energy grade line. HW equals the required headwater depth (HW_1). If trash racks are used, add trash rack losses to HW_1 .

Outlet Control: The outlet control calculations result in the headwater elevation required to convey the design discharge through the selected culvert if the culvert is operating in outlet control. The critical depth charts and outlet control nomographs of Section 5.2.4 are used in the design process. For illustration, refer to the schematic critical depth chart and outlet control nomograph shown in Figures 5.12 and 5.13, respectively.

1. Determine the tailwater depth above the outlet invert (TW) at the design flow rate. This is obtained from backwater or normal depth calculations of the downstream channel, or from field observations. Field observations are important in determining tailwater depths. The area downstream of the culvert should be examined for features that may create backwater effects, i.e., channel control, another culvert, etc. If such features are found, appropriate backwater analysis techniques should be employed to determine the tailwater depth. When culverts are in series, the headwater elevation from the downstream culvert should be checked to make sure that it doesn't back up water affecting the outlet conditions of the upstream culvert.
2. Enter the appropriate critical depth chart (Figure 5.12) with the flow rate and read the critical depth (d_c). If the computed d_c is greater than D , use D for critical depth. d_c cannot exceed the top of the culvert.

(Note: The d_c curves are truncated for convenience when they converge. If an accurate d_c is required for $d_c \gg 0.9D$, consult the *Handbook of Hydraulics* by Brater and King, or other hydraulic references.)

3. Calculate $(d_c + D)/2$
4. Determine the depth from the culvert outlet invert to the hydraulic grade line (h_o).

$$h_o = TW \text{ or } (d_c + D)/2, \text{ whichever is larger} \quad (5.6)$$

5. From Table 5.3 (page 5-32) obtain the appropriate entrance loss coefficient, K_e , for the culvert inlet configuration.

Figure 5.12
Critical Depth Chart (Schematic)
 (USDOT, FHWA, HDS-5, 1985)

6. Determine the losses through the culvert barrel, H , using the outlet control nomograph (Figure 5.13) or appropriate equations if outside the range of the nomograph.
 - a) If the Manning's n value given in the outlet control nomograph is different than the Manning's n for the culvert, adjust the culvert length using the formula:

$$L_1 = L \left(\frac{n_1}{n} \right)^2 \quad (5.7)$$

Then use L_1 rather than the actual culvert length when using the outlet control nomograph.

- b) Using a straightedge, connect the culvert size (point 1) with the culvert length on the appropriate K_e scale (point 2). This defines a point on the turning line (point 3).
 - c) Again using the straightedge, extend a line from the discharge (point 4) through the point on the turning line (point 3) to the Head Loss (H) scale. Read H, which is the energy loss through the culvert, including entrance, friction, and outlet losses.
 - d) All other applicable losses should be added to H.
7. Calculate the required outlet control headwater elevation.

$$EL_{ho} = EL_o + H + h_o \quad (5.8)$$

where EL_o is the invert elevation at the outlet.

8. If the outlet control headwater elevation exceeds the design headwater elevation, a new culvert configuration must be selected and the process repeated. Generally, an enlarged barrel will be necessary since inlet improvements are of limited benefit in outlet control.

Evaluation of Results: Compare the headwater elevations calculated for inlet and outlet control. The higher of the two is designated the controlling headwater elevation. The culvert can be expected to operate with that higher headwater for at least part of the time.

The outlet velocity is calculated as follows:

1. If the controlling headwater is based on inlet control, determine the normal depth and velocity in the culvert barrel. The velocity at normal depth is assumed to be the outlet velocity (Figure 5.14). Normal depth for circular and rectangular culverts can be found using Figure 5.19 (page 5-33).
2. If the controlling headwater is in outlet control, determine the area of flow at the outlet based on the barrel geometry (see Figure 5.15) and the following:
 - a) Critical depth, if the tailwater is below critical depth.
 - b) The tailwater depth if the tailwater is between critical depth and the top of the barrel.
 - c) The height of the barrel if the tailwater is above the top of the barrel.

Repeat the design process until an acceptable culvert configuration is determined. Once the barrel is selected it must be fitted into the roadway cross section. The culvert barrel

Figure 5.13
Outlet Control Nomograph (Schematic)
(USDOT, FHWA, HDS-5, 1985)

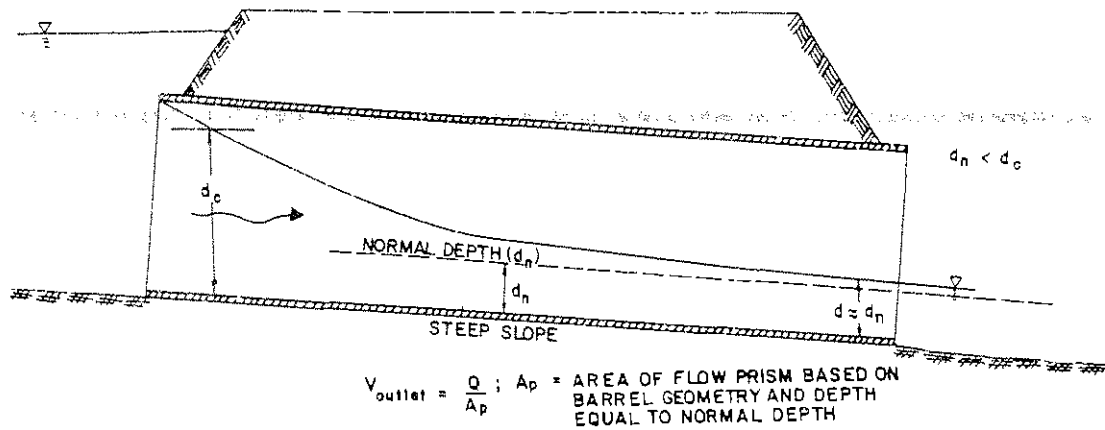

Figure 5.14
Outlet Velocity - Inlet Control
 (USDOT, FHWA, HDS-5, 1985)

Figure 5.15
Outlet Velocity - Outlet Control
 (USDOT, FHWA, HDS-5, 1985)

must have adequate cover, the length should be close to the approximate length, and the headwalls and wingwalls must be dimensioned.

If outlet control governs and the headwater depth (referenced to the inlet invert) is less than $1.2D$, it is possible that the barrel flows partly full through its entire length. In this case, caution should be used in applying the approximate method of setting the downstream elevation based on the greater of tailwater or $(d_c + D)/2$. If an accurate headwater is necessary, backwater calculations should be used to check the result from the approximate method. If the headwater depth falls below $0.75D$, the approximate method should not be used.

If the selected culvert will not fit the site, return to the culvert design process and select another culvert. If neither tapered inlets nor flow routing are to be applied, document the design. Culvert design shall include a performance curve which displays culvert behavior over a range of discharges. Development of performance curves is presented in Section 5.2.3.3 and example problem number 4 in Section 5.2.5.4 (page 5-60) contains a performance curve calculation.

5.2.3.2 Special Culvert Conditions:

Storage Routing: A significant storage capacity behind a highway embankment attenuates a flood hydrograph. Because of the reduction of the peak discharge associated with this attenuation, the required capacity of the culvert, and its size, may be reduced considerably in some cases. The reduced size may well justify some increase in the hydrologic design effort.

All reservoir routing procedures require three basic data inputs: 1) an inflow hydrograph; 2) an elevation versus storage relationship; and 3) an elevation versus discharge relationship. A complete inflow hydrograph, not just the peak discharge, must be generated. Elevation, often denoted as stage, is the parameter which relates storage to discharge providing the key to the storage routing solution.

Elevation versus storage data can be obtained from a topographic map of the culvert site. The area enveloped by each contour line is planimetered and recorded. The average area between each set of contour lines is obtained and multiplied by the contour interval to find the incremental volume. These incremental volumes are added together to find the accumulated volume at each elevation. These data can then be plotted, as stage versus storage.

Elevation versus discharge data can be computed from culvert data and the roadway geometry as described elsewhere in this section. Discharge values for the selected culvert and overtopping flows are tabulated with reference to elevation. The combined discharge is utilized in the formulation of a performance curve.

Despite the consideration of storage routing, the selection of an appropriate culvert size for a given set of hydrologic and site conditions is the design objective. However, in order to perform the storage routing calculations, a culvert must first be selected.

Storage routing calculations will then be required to verify the selected size. *Hydraulic Design of Highway Culverts* (USDOT, FHWA, HDS No. 5, 1985), contains a procedure to aid in selecting an initial culvert size based on an estimated peak discharge achieved from storage routing.

The storage-indication method of flood routing is used to establish the outflow hydrograph and attenuated peak discharge resulting from the embankment storage. Section 8.8 describes the application of the storage-indication method and contains a flood routing example.

Culverts With Drop Inlets: When culverts have drop inlets, normal culvert design nomographs are not applicable. The water falling into the catch basin causes significant turbulence and energy losses. For this condition the analysis for a storm drain inlet should be used.

Detention Basin Outlets: Culverts are frequently used for detention basin outlet structures. The culvert design methods presented in this section can be used to develop the stage-discharge relationship for these structures. If the detention basin discharges into a storm drain system, procedures from Section 4.2 should be used to establish the hydraulic grade line for that storm drain to check for outlet control.

5.2.3.3 Performance Curves: Performance curves are representations of flow rate versus headwater depth or elevation for a culvert. Because a culvert has several possible control sections (inlet, outlet, throat), a given installation will have a performance curve for each control section and one for roadway overtopping. The overall culvert performance curve is made up of the controlling portions of the individual performance curves for each control section.

Inlet Control: The inlet control performance curves are developed using the inlet control nomographs of Section 5.2.4. The headwaters corresponding to the series of flow rates are determined and then plotted. The transition zone is inherent in the nomographs.

Outlet Control: The outlet control performance curves are developed using the outlet control nomographs of Section 5.2.4. Flows bracketing the design flow are selected. For these flows, the total losses through the barrel are calculated or read from the outlet control nomographs. The losses are added to the elevation of the hydraulic grade line at the culvert outlet to obtain the headwater.

If backwater calculations are performed beginning at the downstream end of the culvert, friction losses are accounted for in the calculations. Adding the inlet loss to the energy grade line in the barrel at the inlet results in the headwater elevation for each flow rate. An example of development of a performance curve is contained in Section 5.2.5.4.

Roadway Overtopping: A performance curve showing the culvert flow as well as the flow across the roadway is a useful analysis tool. Rather than using a trial and error procedure to determine the flow division between the overtopping flow and the culvert

Figure 5.16
Culvert Performance Curve with Roadway Overtopping
 (USDOT, FHWA, HDS-5, 1985)

flow, an overall performance curve can be developed. The performance curve depicts the sum of the flow through the culvert and the flow across the roadway.

The overall performance curve can be determined by performing the following steps:

1. Select a range of flow rates and determine the corresponding headwater elevations for the culvert flow alone. These flow rates should fall above and below the design discharge and cover the entire flow range of interest. Both inlet and outlet control headwaters should be calculated. It is recommended that the 2-, 10-, and 50-year flow rates be used for developing the performance curve below the headwater depth where roadway overtopping begins.

2. Combine the inlet and outlet control performance curves to define a single performance curve for the culvert.
3. When the culvert headwater elevations exceed the roadway crest elevation, overtopping will begin. Calculate the equivalent upstream water surface depth above the roadway (crest of weir) for each selected flow rate. Use these water surface depths and Equation 5.9 to calculate flow rates across the roadway.
4. Add the culvert flow and the roadway overtopping flow at the corresponding headwater elevations to obtain the overall culvert performance curve.

Using the combined culvert performance curve, it is an easy matter to determine the headwater elevation for any flow rate, or to visualize the performance of the culvert installation over a range of flow rates. When roadway overtopping begins, the rate of headwater increase will flatten severely. The headwater will rise very slowly from that point on. Figure 5.16 depicts an overall culvert performance curve with roadway overtopping. Example problem number 4 in Section 5.2.5 illustrates the development of an overall culvert performance curve. The 100-year discharge should be identified on the performance curve and the corresponding depth of flow over the roadway.

The Federal Highway Administration's computer program, HY8, can be used in the development of performance curves. The U.S. Army Corps of Engineers HEC-2 and HEC-RAS computer programs are also capable of analyzing culverts.

5.2.3.4 Roadway Overtopping: Roadway overtopping will begin as the headwater rises to the elevation of the lowest point of the roadway. This type of flow is similar to flow over a broad crested weir. The length of the weir can be taken as the horizontal length across the roadway. The flow across the roadway is calculated from the broad crested weir equation:

$$Q_o = K_t C_r L_x (HW_r)^{1.5} \quad (5.9)$$

The charts in Figure 5.17 indicate how to evaluate the correction factors K_t and C_r .

If the elevation of the roadway crest varies, for instance where the crest is defined by a roadway sag vertical curve, the vertical curve can be approximated as a series of horizontal segments. The flow over each is calculated separately and the total flow across the roadway is the sum of the incremental flows for each segment (Figure 5.18).

The total flow across the roadway then equals the sum of the roadway overflow plus the culvert flow. A performance curve must be plotted including both culvert flow and road overflow. The headwater depth for a specific discharge, such as the 100 year discharge can then be read from the curve. Design example 4 in Section 5.2.5 illustrates this procedure.

$$C_d = K_t C_r$$

5.2.4 Design Aids

The Culvert Design Form (Figure 5.10, page 5-19) has been formulated to guide the user through the design process. Summary blocks are provided at the top of the form for the project description, and the designer's identification. Summaries of hydrologic data of the form are also included. At the top right is a small sketch of the culvert with blanks for inserting important dimensions and elevations.

The central portion of the design form contains lines for inserting the trial culvert description and calculating the inlet control and outlet control headwater elevations. Space is provided at the lower center for comments and at the lower right for a description of the culvert barrel selected. The design chart should be completely filled out, including consideration of inlet and outlet control.

Table 5.3 and Figures 5.19 through 5.38 should facilitate completion of the Culvert Design Form.

5.2.5 Design Examples

The following example problems are from HDS-5 (USDOT, FHWA, 1985) and illustrate the use of the design methods and charts for selected culvert configurations and hydraulic conditions. The problems cover the following situations:

- Problem No. 1: Circular pipe culvert, standard 2-2/3 by 1/2 inch (6.8 by 1.3 cm) CMP with beveled edge or reinforced concrete pipe with groove end. No FALL.
- Problem No. 2: Reinforced cast-in-place concrete box culvert with square edges and with bevels. No FALL.
- Problem No. 3: Elliptical pipe culvert with groove end and a FALL.
- Problem No. 4: Roadway overtopping calculations and performance curve development.

5.2.5.1 Example Problem No. 1: A culvert at a new roadway crossing must be designed to pass the 25-year flood. Hydrologic analysis indicates a peak flow rate of 200 cfs. Use the following site information:

- » Elevation of stream bed at Culvert Face: 100 ft
- » Natural Stream Bed Slope: 1 percent = 0.01 ft/ft
- » Tailwater for 25-Year Flood: 3.5 ft
- » Approximate Culvert Length: 200 ft
- » Shoulder Elevation: 110 ft

Design a circular pipe culvert for this site. Consider the use of a corrugated metal pipe with standard 2-2/3 by 1/2 inch corrugations and beveled edges and concrete pipe with a groove end. Base the design headwater on the shoulder elevation with a 2-foot freeboard (elevation 108.0 ft). Set the inlet invert at the natural streambed elevation (no FALL).

Figure 5.39 represents a completed Culvert Design Form for this example.

Note: Figures 5.20, 5.22, 5.23, 5.24, and Table 5.3 were used in this example.

Example Problem No. 1 Culvert Design Form
(USDOT, FHWA, HDS-5, 1985)

Culverts and Bridges

5.2.5.2 Example Problem No. 2: A new culvert at a roadway crossing is required to pass a 50-year flow rate of 300 cfs. Use the following site conditions:

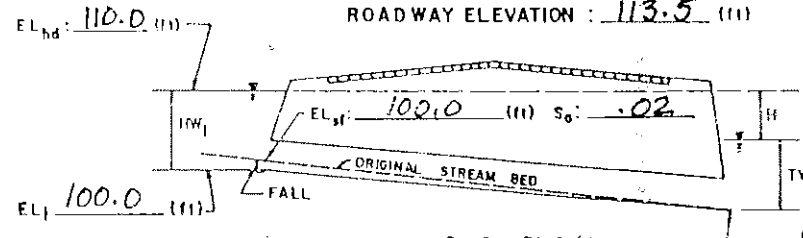

- » EL_{hd} : 110 ft based on adjacent structures
- » Shoulder Elevation: 113.5 ft
- » Elevation of Streambed at Culvert Face (EL_{sf}): 100 ft
- » Natural Stream Slope: 2 percent
- » Tailwater Depth: 4.0 ft
- » Approximate Culvert Length: 250 ft

Design a reinforced concrete box culvert for this installation. Try both square edges and 45 degree beveled edges in a headwall. Do not depress the inlet (no FALL).

Figure 5.40 represents a completed Culvert Design form for Problem No. 2.

Note: Figures 5.26, 5.28, 5.29, 5.30, and Table 5.3 are used in this solution.

5.2.5.3 Example Problem No. 3: Design a culvert to pass a 25-year flow of 180 cfs. Minimum depth of cover for this culvert is 2 feet.

- » EL_{hd} : 105 ft based on adjacent structures
- » Shoulder Elevation: 105.5 ft
- » Elevation of Streambed at Culvert Face (EL_{sf}): 100 ft.
- » Original Stream Slope: 5 percent
- » Tailwater Depth: 4 ft
- » Approximate Culvert Length: 150 ft

Due to the low available cover over the conduit, use a horizontal elliptical concrete pipe. Use of a small depression (FALL) of about 1 ft at the inlet is acceptable.

Refer to 5.41 for a completed Culvert Design Form for this problem.

Note: Figures 5.31, 5.33, 5.35, and Table 5.3 are used in this solution.

Use of FALL in streams carrying a heavy sediment load is not recommended.

5.3 Entrances and Outlets for Culverts and Storm Drains

This section provides guidelines for design of culvert type inlets and outlets to closed conduit systems. Runoff entering and exiting closed conduits may require transitions into and out of the conduit to minimize entrance losses and protect adjacent property and drainage facilities from possible erosion. Pavement drainage inlets that allow runoff to drop into catch basins are discussed in Section 3.3 and are not addressed here.

5.3.1 Interaction with Other Systems

Closed conduit inlets and outlets provide transitions from a ponded or channelized condition upstream into the closed conduit and then back to a channelized condition downstream. Additional channel bank protection may be required in the vicinity of the inlet or outlet to complete the transition to the design velocity and flow depth of the receiving channel. A drop structure may be located upstream or downstream from the closed conduit and should be incorporated into the design. The design of inlets and outlets should take into account all conditions in the upstream and downstream direction to the location where the inlet, outlet, and closed conduit have no effect on predesign flow conditions.

When an open channel, detention or retention basin drains into a storm drain system, culvert type inlets are frequently used. The storm drain hydraulic grade line must be considered when estimating the inlet capacity for culvert type inlets. The storm drain hydraulic grade line at the inlet, with the appropriate entrance loss added, should be substituted for the outlet control headwater elevation normally used for outlet control computations. To determine the controlling headwater, the computed outlet control headwater elevation should be compared with the inlet control headwater elevation obtained from the standard inlet control nomograph.

5.3.2 Special Criteria for Closed Conduits

5.3.2.1 Bank Protection: Roadway embankments with culverts passing through them should be protected from potential damage caused by roadway overtopping during a runoff event in excess of the culvert design capacity. When a planned flow over the road has damage potential, such as when the 100-year discharge causes flow over the roadway, the embankment for both upstream and downstream sides should be protected by paving, grouted riprap, or other means of permanent stabilization.

5.3.2.2 Entrance Structures and Transitions: Criteria for culvert entrances are contained in Section 5.2.2.13. The same criteria apply to culvert type entrances for storm drains. Design considerations include aligning the culvert with the natural channel profile, protection against inlet failure due to buoyant forces, and safety considerations for the public.

Culvert performance can be improved by providing a smooth and gradual transition at the entrance. Improved inlet designs have been developed for culverts operating in inlet control and are presented in Section 5.2.2.

Supercritical flow transitions at inlets require special design consideration. For design of supercritical flow contractions, refer to *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983).

5.3.2.3 Outlet Structures: Standard measures for scour protection at conduit outlets include cutoff walls, wingwalls with aprons, and grouted or ungrouted riprap. These measures should be used as appropriate to ensure that the velocity entering the receiving channel is within the allowable range of velocities for the channel outlet condition. Outlet conditions are classified as follows:

1. *Natural channel outlets* where the existing natural channel is modified only to transition to and from the culvert.
2. *Artificial channel outlets* where the culvert is part of an overall drainage plan and discharges into an improved, artificial channel.
3. *Side channel outlets* where a conduit drains into a larger receiving channel from the side at some angle of confluence.

It is not always desirable to totally restrict the movement of natural channels at the culvert outlet. Limited downstream scour and channel movement may be allowed in some cases. Due to the nature of artificial channel and side channel outlets, scour and bed movement should not be permitted. The following criteria shall be used in determining the type of outlet protection required based on the outlet condition.

Natural Channel Outlets: Natural channel outlet protection is based on the ratio of the culvert outlet velocity to the average natural stream velocity.

1. Culverts with outlet velocities less than or equal to 1.3 times the average natural stream velocity for the design discharge shall require a cutoff wall as a minimum for protection. Design criteria for cutoff walls are presented below.
2. Where the outlet velocity is greater than 1.3 times the natural stream velocity, but less than 2.5 times, a riprap apron should be provided. Design procedures for riprap aprons are in Section 5.3.3.2.
3. When outlet velocities exceed 2.5 times the natural stream velocity, an energy dissipator should be provided. Several energy dissipators are described in Chapter 7.

Artificial Channel and Side Channel Outlets: Artificial channel and side channel outlet protection is based on the ratio of the culvert outlet velocity to the allowable velocity for the channel lining material. Outlet discharge must be transitioned to limit the

velocity to the allowable. Allowable velocities for several channel lining materials are shown in Tables 6.1, 6.2 and 6.3.

1. Conduits with outlet velocity less than or equal to the allowable require no outlet protection.
2. Conduits with outlet velocity greater than one and less than 2.5 times the allowable velocity must be provided with a riprap, concrete, or other suitable apron to transition the velocity to the allowable channel velocity.
3. When outlet velocities exceed 2.5 times the allowable channel velocity, an energy dissipator should be provided. Several energy dissipators are described in Chapter 7.

Cutoff Walls: A cutoff wall placed at the culvert outlet in a natural stream provides adequate protection downstream when the scour will not be excessive, or where the development of a scour hole will not undermine nearby structures so that it is practical to allow localized scour.

The following criteria applicable to cutoff walls is based on the computed scour hole geometry. The procedure for determining the scour hole geometry is presented in Section 5.3.3.1.

1. The depth of the cutoff wall shall be equal to the maximum depth of scour.
2. The width of the cutoff wall shall be a minimum of one-third the maximum scour width.
3. The depth of the cutoff wall should not normally exceed six feet. Where a deeper wall is necessary to meet the above criteria, either another form of protection should be employed or an analysis will be required to substantiate the walls structural stability.

5.3.2.4 Safety: Inlets and outlets to closed conduits may present dangers to the public when access is not controlled. Refer to Section 5.2.2.12 for the safety requirements related to conduit inlets and outlets.

5.3.3 Estimating Erosion at Culvert Outlets

5.3.3.1 Scour Hole Geometry: The objective of this section is to present a method for estimating the amount of erosion at an unprotected culvert (or storm drain) outlet based on soil and flow data and culvert geometry. This section has been adapted from the *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983).

The scour hole geometry varies with tailwater conditions with the maximum scour geometry occurring at tailwater depths less than half the culvert diameter with the maximum depth of scour (h_s) occurring at a location approximately $0.4 L_s$ downstream of the culvert outlet, where L_s is the length of scour.

Empirical equations defining the relationship between the culvert discharge intensity (defined on page 5-71), time, and the length, width, depth, and volume of scour hole are presented for the maximum or extreme scour case. The dimensionless scour hole geometry is shown in Figure 5.45.

Cohesionless Material: The general expression for determining scour geometry in a cohesionless soil for a circular pipe flowing full is:

$$\text{Dimensionless Scour Geometry} = \alpha \left(\frac{Q}{g^{1/2} D^{5/2}} \right)^\beta \left(\frac{t}{t_o} \right)^\theta \quad (5.10)$$

The values for the coefficients α_e , β , and θ , can be found in Table 5.4.

For noncircular or partly full culverts, the diameter D can be replaced by an equivalent depth, y_e :

$$y_e = (A/2)^{1/2} \quad (5.11)$$

A is the cross sectional area of flow. Modifying Equation 5.10 to include the equivalent depth results in the general expression:

$$\text{Dimensionless Scour Geometry} = \alpha_e \left(\frac{Q}{g^{1/2} y_e^{5/2}} \right)^\beta \left(\frac{t}{t_o} \right)^\theta \quad (5.12)$$

where:

$$\alpha_e = \alpha 0.63^{(2.5\beta-1)} \quad \text{for } h_s, W_s, \text{ and } L_s \quad (5.13)$$

$$\alpha_e = \alpha 0.63^{(2.5\beta-3)} \quad \text{for } V_s \quad (5.14)$$

$$\left[\frac{h_s}{D}, \frac{W_s}{D}, \frac{L_s}{D}, \text{ or } \frac{V_s}{D^3} \right] = \alpha \left(\frac{Q}{\sqrt{g} D^{5/2}} \right)^\beta \left(\frac{t}{t_0} \right)^\theta$$

where $t_0 = 316$ min.

V-2. For Other Culvert Shapes. Same material as above:

$$\left[\frac{h_s}{y_e}, \frac{W_s}{y_e}, \frac{L_s}{y_e}, \text{ or } \frac{V_s}{y_e^3} \right] = \alpha_e \left(\frac{Q}{\sqrt{g} y_e^{5/2}} \right)^\beta \left(\frac{t}{t_0} \right)^\theta$$

where $t_0 = 316$ min.

V-3. For Circular Culverts. Cohesive sandy clay with PI = 5-16:

$$\left[\frac{h_s}{D}, \frac{W_s}{D}, \frac{L_s}{D}, \text{ or } \frac{V_s}{D^3} \right] = \alpha \left(\frac{\rho V^2}{\tau_c} \right)^\beta \left(\frac{t}{t_0} \right)^\theta$$

where $t_0 = 316$ min.

V-4. For Other Culvert Shapes. Cohesive sandy clay with PI = 5-16:

$$\left[\frac{h_s}{y_e}, \frac{W_s}{y_e}, \frac{L_s}{y_e}, \text{ or } \frac{V_s}{y_e^3} \right] = \alpha_e \left(\frac{\rho V^2}{\tau_c} \right)^\beta \left(\frac{t}{t_0} \right)^\theta$$

where $t_0 = 316$ min.

Gradation: The cohesionless bed materials presented in Table 5.4 are categorized as either uniform (U) or graded (G). The grain size distribution is determined by performing a sieve analysis (ASTM DA22-63). The standard deviation (σ) is computed as:

$$\sigma = (d_{84}/d_{16})^{1/2} \quad (5.15)$$

where the values of d_{84} and d_{16} are extracted from the grain size distribution. If $\sigma \leq 1.5$, the material is considered to be uniform; if $\sigma > 1.5$, the material is classified as graded.

Cohesive Soils: If the cohesive soil is a sandy clay similar to the one tested at Colorado State University by Abt, et al, Equations 5.10 or 5.12 and the appropriate coefficients in Table 5.4 can be used to estimate the scour hole dimensions. The sandy clay tested had 58 percent sand, 27 percent clay, 15 percent silt, and 1 percent organic matter; had a mean grain size of 0.15 mm, and had a plasticity index (PI) of 15.

Since Equations 5.10 and 5.12 do not include soil characteristics, they can only be used for soils similar to the ones tested. Shear number expressions, that related scour to the critical shear stress of the soil, were derived to have a wider range of applicability for cohesive soils besides the one specific sandy clay that was tested.

The shear number expressions for circular culverts are:

$$h_s/D, W_s/D, L_s/D, \text{ or } V_s/D^3 = \alpha (\rho V^2/\tau_c)^\beta (t/t_o)^\theta \quad (5.16)$$

and for other shaped culverts:

$$h_s/y_e, W_s/D, L_s/y_e, \text{ or } V_s/y_e^3 = \alpha_e (\rho V^2/\tau_c)^\beta (t/t_o)^\theta \quad (5.17)$$

where:

$$\alpha_e = \alpha/(0.63) \quad \text{for } h_s, W_s, \text{ and } L_s \quad (5.18)$$

$$\alpha_e = \alpha/(0.63)^3 \quad \text{for } V_s \quad (5.19)$$

The values of the coefficients α , β , θ and α_e in Equations 5.16 and 5.17 are presented in Table 5.4.

The critical tractive shear stress is defined as:

$$\tau_c = 0.001(S_v + 180) \tan(30 + 1.73PI) \quad (5.20)$$

where S_v is the saturated shear strength in pounds per square inch and PI is the Plasticity Index from the Atterberg limits.

It is recommended that Equations 5.16 and 5.17 be limited to sandy clay soils with a plasticity index of 5 to 16.

Time of Scour: The time of scour is estimated based upon a knowledge of peak flow duration. Lacking this knowledge, it is recommended that a time of 30 minutes be used in Equations 5.10, 5.12, 5.16, and 5.17. The tests indicate that approximately two-thirds to three-fourths of the maximum scour occurs in the first 30 minutes of the flow duration.

It should be noted that the exponents for the time parameter in Table 5.4 reflect the relatively flat part of the scour-time relationship and are not applicable for the first 30 minutes of the scour process.

Headwalls: Installation of headwalls flush with the culvert outlet moves the scour hole downstream. However, the magnitude of the scour geometries remain essentially the same as for the case without the headwall. The headwall should extend to a depth equal to the maximum depth of scour.

Summary: The prediction equations presented in this section are intended to serve along with field reconnaissance as guidance for determining the need for energy dissipators at culvert outlets. Remember that the equations assume that grade control exists whether it be manmade or natural, and do not include long-term channel degradation of the downstream channel. The equations are based on tests which were conducted to determine maximum scour for the given condition and therefore represent what might be termed worst case scour geometries. The procedure presented is from *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983).

5.3.3.2 Scour Hole Geometry Calculation Procedures:

For Cohesionless and Cohesive Soils:

1. Using the appropriate methodology from Volume I, Hydrology, perform a hydrologic analysis of the drainage path in which the culvert is located or is to be placed. Estimate the magnitude and duration of the peak discharge. Express the discharge in cfs and the duration in minutes then determine the discharge intensity and equivalent depth.

The discharge intensity is:

$$D.I. = Q / (g^{1/2} D^{5/2}) \quad \text{Circular culverts flowing full}$$

$$D.I. = Q / (g^{1/2} y_e^{5/2}) \quad \text{for other shapes}$$

where Equation 5.11 is used to determine the equivalent depth:

$$y_e = (A/2)^{1/2}$$

For Cohesionless Materials, or 0.15mm Sandy Clay:

2. Compute the discharge intensity when the culvert is flowing at the peak discharge.
3. Determine scour coefficients from Table 5.4.
4. Use Equation 5.10 or 5.12 to compute the scour hole dimensions with $t_0=316$:

$$h_s/D, W_s/D, L_s/D, \text{ or } V_s/D^3 = \alpha \left(\frac{Q}{g^{1/2} D^{5/2}} \right)^\beta \left(\frac{t}{316} \right)^\theta$$

$$h_s/y_e, W_s/y_e, L_s/y_e, V_s/y_e^3 = \alpha_e \left(\frac{Q}{g^{1/2} y_e^{5/2}} \right)^\beta \left(\frac{t}{316} \right)^\theta$$

For Other Cohesive Materials with PI From 5 to 16:

2. a. Compute the culvert outlet velocity in ft/sec.
- b. Obtain a soil sample at the proposed culvert location.
- c. Perform Atterberg limits tests and determine the plasticity index, PI (ASTM D423-36).
- d. Saturate a sample and perform an unconfined compressive test (ASTM D211-66-76) to determine the saturated shear stress, S_v , lb/in².

- e. Compute the critical tractive shear strength, τ_c , from Equation 5.20.
 - f. Compute the modified shear number, $Sn_{mod} (\rho V^2 / \tau_c)$.
3. Determine scour coefficients from Table 5.4.
 4. Use equation 5.16 or 5.17 to compute the desired scour hole dimensions, use $t_0 = 316$ minutes.

For circular culverts:

$$h_s/D, W_s/D, L_s/D, \text{ or } V_s/D^3 = \alpha(\rho V^2 / \tau_c)^\beta (t/316)^\theta$$

or, for noncircular culverts:

$$h_s/y_e, W_s/y_e, L_s/y_e, \text{ or } V_s/y_e^3 = \alpha_e(\rho V^2 / \tau_c)^\beta (t/316)^\theta$$

Two example problems on the computation of the geometry of the scour hole are presented in the next section. The example problems are from HEC-14 (USDOT, FHWA, 1983).

5.3.3.3 Example Scour Hole Calculations for Cohesionless Material: Determine the scour geometry—maximum depth, width, length and volume of scour—for a proposed circular 30-inch C.M.P. discharging an estimated 50 cfs when flowing full. The downstream channel is composed of a graded gravel material.

1. The duration of the peak discharge of 50 cfs is not known. Therefore, a peak flow duration of 30 minutes will be estimated.
2. The circular, 30-inch C.M.P. at 50 cfs will have a discharge intensity of

$$D.I. = 50 / (g^{1/2} (30/12)^{5/2}) = 50 / ((5.67)(2.5)^{5/2}) = \underline{0.89}$$

3. The coefficients of scour obtained from Table 5.4 are:

	α	β	θ
Depth of Scour	1.49	0.50	0.03
Width of Scour	8.76	0.89	0.10
Length of Scour	13.09	0.62	0.07
Volume of Scour	42.31	2.28	0.17

4. Using Equation 5.10 with $t_0 = 316$ minutes, the scour hole dimensions are:

$$h_s/D, W_s/D, L_s/D, \text{ or } V_s/D^3 = \alpha (Q/g^{1/2} D^{5/2})^\beta (t/316)^\theta$$

$$\text{Depth: } h_s/D = 1.49 (0.89)^{0.50} (0.09)^{0.03}$$

$$h_s = (1.49)(0.89)(2.5) = \underline{3.28 \text{ ft}}$$

$$\text{Width: } W_s/D = 8.76 (0.89)^{0.89} (0.09)^{0.10}$$

$$W_s = (6.21)(2.5) = \underline{15.5 \text{ ft}}$$

$$\text{Length: } L_s/D = 13.09 (0.89)^{0.62} (0.09)^{0.07}$$

$$L_s = (10.29)(2.5) = \underline{25.72 \text{ ft}}$$

$$\text{Volume: } V_s/D^3 = 42.31 (0.89)^{2.28} (0.09)^{0.17}$$

$$V_s = (21.54)(15.63) = \underline{336.67 \text{ ft}^3}$$

5. Using Figure 5.45, the location of the maximum scour is defined as occurring at:

$$0.4(L_s) = 0.4 (25.72) = \underline{10.3 \text{ ft}} \text{ downstream of the culvert outlet.}$$

5.3.3.4 Example Scour Hole Calculations for a Cohesive Material: Determine the scour geometry, maximum depth, width, length, and volume of scour for an existing circular 24-inch C.M.P. discharging an estimated 40 cfs when flowing full. The downstream channel is composed of a sandy-clay material.

1. The duration of the peak discharge of 40 cfs is not known. Therefore, a peak flow duration of 30 minutes will be estimated.

2. a. The average velocity at the culvert outlet is:

$$V = Q/A = 40.0/3.14 = \underline{12.74 \text{ fps}}$$

- b-e. The sandy-clay material was tested and found to have a PI of 12 and a saturated shear strength (S_v) of 240 psi. The critical tractive shear can be estimated by substituting into Equation 5.20.

$$\tau_c = 0.001(240 + 180) \tan(30 + 1.73(12))$$

$$\tau_c = 0.001(420) \tan(50.76) = \underline{0.51 \text{ lb/ft}^2}$$

f. The modified shear number $Sn_{\text{mod}} = (\rho V^2 / \tau_c)$ is:

$$Sn_{\text{mod}} = 1.94 (12.74)^2 / 0.51 = \underline{617.4}$$

3. The experimental coefficients α , β , θ from Table 5.4 are:

	α	β	θ
Depth	0.86	0.18	0.10
Width	3.55	0.17	0.07
Length	2.82	0.33	0.09
Volume	0.62	0.93	0.23

4. Using Equation 5.16 with $t_o = 316$ minutes, the scour hole dimensions are:

$$h_s/D, W_s/D, L_s/D, \text{ or } V_s/D^3 = \alpha (\rho V^2 / \tau_c)^\beta (t/316)^\theta$$

$$\text{Depth: } h_s/D = 0.86 (617.4)^{0.18} (0.09)^{0.10}$$

$$h_s = (2.14)(2) = \underline{4.30 \text{ ft}}$$

$$\text{Width: } W_s/D = 3.55 (617.4)^{0.17} (0.09)^{0.07}$$

$$W_s = (8.94)(2) = \underline{17.9 \text{ ft}}$$

$$\text{Length: } L_s/D = 2.82 (617.4)^{0.33} (0.09)^{0.09}$$

$$L_s = (18.92)(2) = \underline{37.8 \text{ ft}}$$

$$\text{Volume: } V_s/D^3 = 0.62 (617.4)^{0.93} (0.09)^{0.23}$$

$$V_s = (140.3)(8) = \underline{1122.5 \text{ ft}^3}$$

5. Location of maximum depth of scour (Figure 5.45)

$$0.4 L_s = 0.4(37.8) = \underline{15.1 \text{ ft}} \text{ downstream of culvert outlet.}$$

5.3.4 Protection at Culvert Outlets

5.3.4.1 Riprap Apron: Riprap aprons placed downstream of culverts provide protection against scour immediately around the culvert as well as providing for the uniform spreading of the flow and decreasing the flow velocity, thus mitigating downstream damages.

These riprap aprons may be designed as simple horizontal aprons as shown in Figure 5.46, with tapered sides of 2:1 for minimum tailwater and 5:1 for maximum tailwater. Minimum tailwater is assumed when the tailwater depth is less than half the culvert height. Maximum tailwater is assumed when the tailwater depth is greater than half the culvert height.

A simplified approach for providing protection downstream of culverts is presented in the next two sections. For more thorough methods see Section 7.4.

5.3.4.2 Riprap Apron Dimension Design Procedures:

1. The length of the apron (L_a) is determined using the following empirical relationships that were developed for the U.S. Environmental Protection Agency (1976):

$$L_a = \frac{1.8Q}{D^{3/2}} + 7D \quad \text{for } TW < \frac{D}{2} \quad (5.21)$$

and:

$$L_a = \frac{3Q}{D^{3/2}} + 7D \quad \text{for } TW > \frac{D}{2} \quad (5.22)$$

where D is the maximum inside culvert width (ft), Q is the pipe discharge (cfs), and TW is the tailwater depth (ft).

2. Where there is no well defined channel downstream of the apron, the width, W_a , of the outlet and of the apron (as shown in Figure 5.46) should be as follows:

$$W_a = 3D + 0.4L_a \quad \text{for } TW \geq \frac{D}{2} \quad (5.23)$$

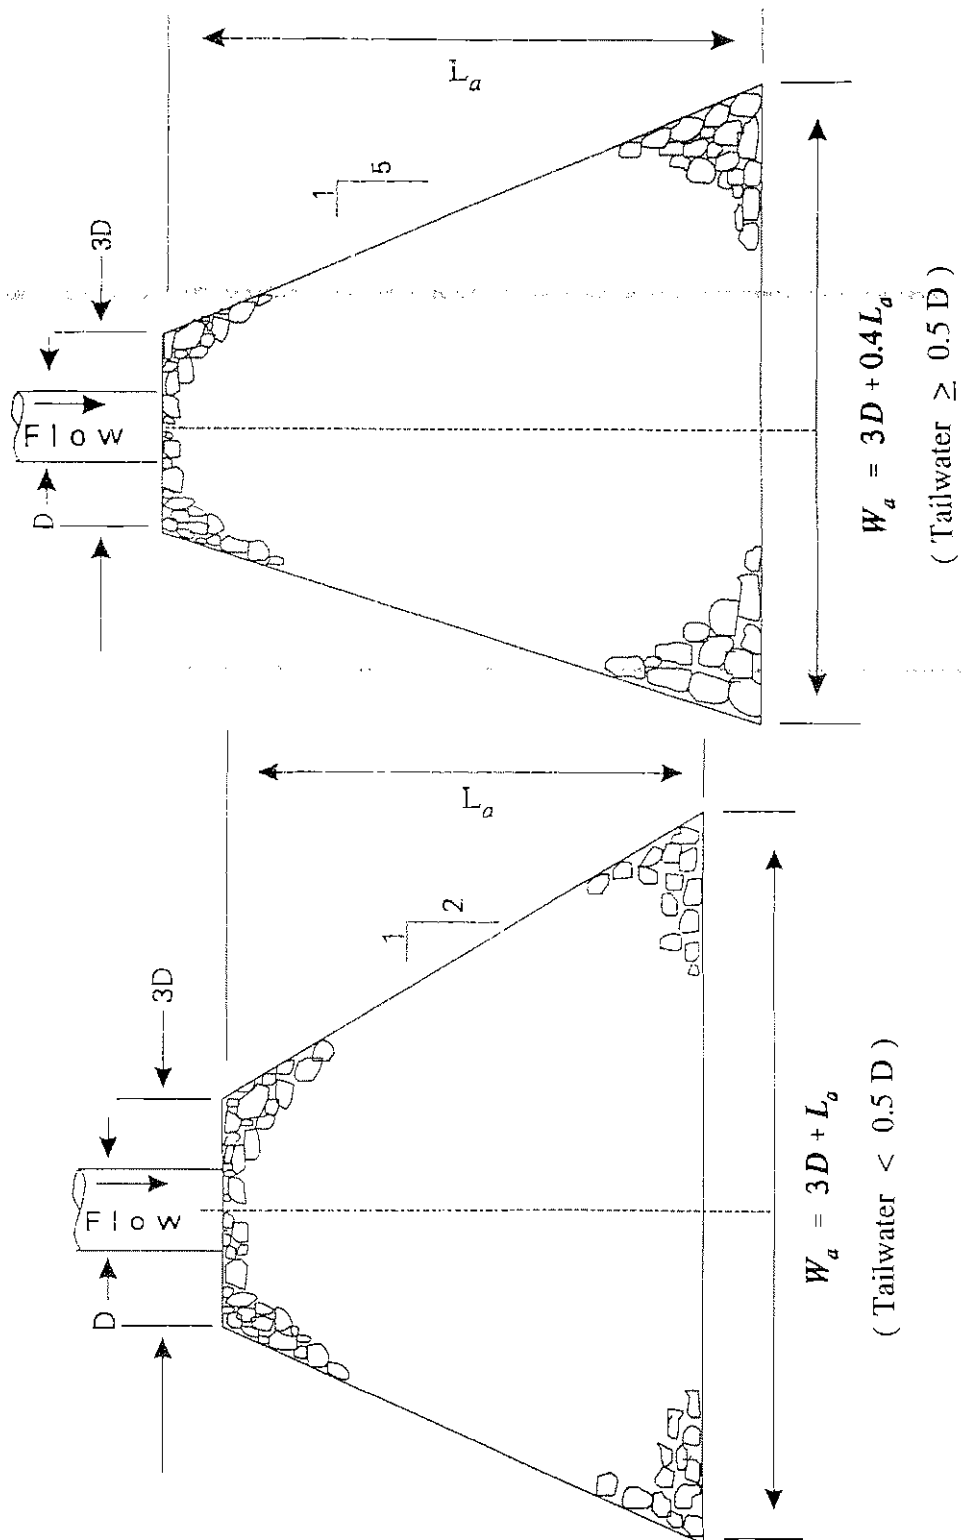

Figure 5.46
Configuration of Conduit Outlet Protection
 (U.S. EPA, 1976)

and:

$$W_a = 3D + L_a \quad \text{for } TW < \frac{D}{2} \quad (5.24)$$

The width of the apron at the culvert outlet should be at least 3 times the culvert width.

3. Where there is a well-defined channel downstream of the apron, the bottom width of the apron should be at least equal to the bottom width of the channel and the lining should extend at least one foot above the tailwater elevation and at least two-thirds of the vertical conduit dimension above the invert.
4. The side slopes should be 2:1 or flatter.
5. The bottom grade should be level.
6. There should be overfall at the end of the apron or culvert.

5.3.4.3. Riprap Apron Stone Size:

1. The median stone diameter (d_{50}) is determined from the following equation:

$$d_{50} = \frac{0.02(Q)^{4/3}}{TW(D)} \quad (5.25)$$

2. Existing scour holes may be used where flat aprons are impractical. Figure 5.47 shows the general design of a scour hole. The stone diameter is determined using the following equations:

$$d_{50} = \frac{0.0125(Q)^{4/3}}{TW(D)} \quad \text{for } y_s = \frac{D}{2} \quad (5.26)$$

also,

$$d_{50} = \frac{0.0082(Q)^{4/3}}{TW(D)} \quad \text{for } y_s = D \quad (5.27)$$

where y_s is the depth of the scour hole below the culvert invert. If the depth of scour isn't known it can be determined using the procedures in Section 5.3.3.1.

3. The other riprap or gabion requirements are as indicated in Chapter 6 for channel linings.
4. Filter fabric or granular bedding shall be provided under riprap or gabion apron protection.

Figure 5.47
Preformed Scour Hole (a) plan and (b) section
 (ASCE, 1975)

5.4 Inverted Siphons

5.4.1 General

Because of the resulting physical conditions, inverted siphons are rarely used in urban drainage; however, due to the flat topography and a large number of canals in Maricopa County, the designer may have to consider using an inverted siphon.

Inverted siphons are used to convey water by gravity under canals, roads, railroads, other structures, and depressions. An inverted siphon is a closed conduit designed to run full and under pressure. When flowing at design capacity, the structure should operate without excess head.

For canal structures, inverted siphons are economical, easily designed and built, and have proven to be a reliable means of water conveyance. However, because of sediment and debris present in stormwater, maintenance can be a significant negative factor. In addition, canals run more or less continually and can be drained between periods of use, but inverted siphons for stormwater do not operate on a regular cycle. If water is left to stand, significant health hazards could result. Inverted siphons shall be considered only when permitted by the jurisdictional agency.

5.4.2 Design Criteria

All pipe should be designed for water-tight joints. Velocity in the conduit should be a minimum of 5.0 fps to prevent sedimentation. The minimum cover over the conduit should exceed 3.0 feet. Inlet and outlet structures are required, and the facility shall meet the requirements for safety described in Section 5.2.2.12. Pipe collars and blow-off structures may be required as determined by the jurisdictional agency. Air vents, after the entrance, should be used unless the agency agrees with eliminating the vents.

At a minimum, the designer should compute losses for the entrance and outlet (including trash racks), pipe friction, and losses at bends and transitions.

5.4.3 Design Procedure

A design procedure and design examples are contained in *Design of Small Canal Structures* (USBR 1974). Taking into consideration conditions that are more specific to urban drainage described before, this publication can be used for most applications in Maricopa County.

5.5 Bridges

This section presents a brief overview of the hydraulic analyses for bridge crossings over open channels. A general discussion of scour is also presented. Comprehensive guidelines and criteria for hydraulic analyses of bridge crossings are beyond the scope of this manual. The reader should refer to appropriate texts and technical handbooks for further information on this subject.

Roadways must often cross open channels in urban areas, therefore, sizing the bridge openings is of paramount importance. In general, bridges should be designed to have as little effect as possible upon the flow passing beneath them. If possible, bridges over natural or man-made channels should be designed so that there is no disturbance to the flow whatsoever. Whenever piers are used, they need to be oriented parallel to flow. Impacts upon channels and floodplains created by bridges usually take the form of increased flow velocities through and downstream of the bridges, increased scour and upstream ponding due to backwater effects. These impacts can cause flood damage to the channel, to adjacent property and to the bridge structure itself.

A new or replacement bridge will not be permitted to create a rise in the existing water surface elevation, to cause an increase in lateral extent of the floodplain, or to otherwise worsen existing conditions.

5.5.1 Hydraulic Analysis

The hydraulic analyses of pre- and post-bridge conditions can be performed using a computerized step-backwater model. The HEC-2 program developed by the U.S. Army Corps of Engineers (USACE, 1990) is the most common backwater computation software available and is used nationwide. The Corps also recently released their HEC-RAS computer program (USACE, 1995a, and 1995b) which is capable of analyzing bridges.

An analytical methodology for hydraulic analysis of bridge crossings is that described in *Hydraulics of Bridge Waterways* (USDOT, FHWA, HDS-1, 1978b).

Another widely-used computer program is WSPRO (USDOT, FHWA, HY-7, 1988) which incorporates the procedures of the HDS-1. A useful publication to accompany WSPRO is *Bridge Waterways Analysis Model Research Report* (USDOT, FHWA, 1986).

Bridge analysis requires meticulous input preparation for proper analysis, care should be taken to review input data and to examine results thoroughly for reasonableness.

If there is a good possibility of debris collecting on the piers, it may be advisable to use a value greater than the pier width to account for debris blockage. However, modeling of debris blockage should be reviewed with the jurisdictional agency.

5.5.2 Hydraulic Design Considerations

Additional factors to be considered in the design of a bridge crossing include flow regime (i.e., subcritical or supercritical flow), anticipated scour effects, and freeboard.

5.5.2.1 Freeboard: Freeboard at a bridge is the vertical distance between the design water surface elevation and the low-chord of the bridge. The bridge low-chord is the lowest portion of the bridge deck superstructure. The purpose of freeboard is to provide room for the passage of floating debris, to provide extra area for conveyance in the event that debris build-up on the piers reduces hydraulic capacity of the bridge, and to provide a factor of safety against the occurrence of waves or floods larger than the design flood.

Bridges should be designed to have a minimum freeboard of two feet for the 100-year event. The structural design of the bridge should take into account the possibility of debris and/or flows impacting the bridge.

In certain cases, site conditions or other circumstances may limit the amount of freeboard at a particular bridge crossing. An example would be the replacement of a "perched" bridge across a natural watercourse where major flows overtop the roadway approaches. In general, variances to the minimum freeboard requirement will be evaluated on a case by case basis by the jurisdictional agency.

5.5.2.2 Supercritical Flow:

For the special condition of supercritical flow within a lined channel, the bridge structure should not affect the flow at all. That is, there should be no projections, piers, etc. in the channel area. The bridge opening should clear and permit the flow to pass unimpeded and unchanged in cross section.

5.5.2.3 Scour: To determine scour at bridges, refer to *Predicting Scour at Bridge Piers and Abutments* (Laursen, 1980) and *HEC No. 18, Evaluating Scour at Bridges* (USDOT, FHWA, 1991). Total scour at a bridge crossing consists of three components which are generally cumulative, and a fourth, lateral stream migration, which can move the general bed grade horizontally to a new location. The first three components are:

Long Term Aggradation or Degradation: This is a variation to river bed elevation, usually occurring over long periods of time due to changes in controls, such as dams and in-stream mining. Such variation can result in modification of sediment discharge and river geomorphology, such as a departure from a meandering to a braided stream. The changes may be natural or man-induced, but are far more often documented as the latter (USDOT, FHWA, 1978a).

Long term bed elevation changes (aggradation or degradation) may be the natural trend of the stream or may be the result of some modification to the stream or watershed condition. Factors that affect long term bed elevation changes are: dams and reservoirs (upstream or downstream of the bridge), changes in watershed land use (urbanization, deforestation, etc.), channelization, cutoff of a meander bend (natural or man-made), changes in the downstream base level (control) of the bridge reach, gravel mining from the stream bed, diversion of water into or out of the stream, natural lowering of the total system, movement of a bend or bridge location in reference to stream platform, and stream movement in relation to the bridge crossing.

General Scour: This type of scour involves the removal of material from the bed and banks across all or most of the width of a channel. The scour is caused by increased velocities and shear stresses caused by the local area geometry and water surface controls.

General scour results from the acceleration of the flow due to either a natural or bridge contraction or both (contraction scour). General scour may also result from the location of the bridge on the stream, such as, its location with respect to a stream bend or its location upstream from the confluence with another stream. In the latter case, the elevation of the downstream water surface will affect the backwater on the bridge, hence, the velocity and scour. General scour may occur during the passage of a flood and the river may fill in as the flood recedes, thus it may not be directly evident; whereas, degradation always results in an evident change that is largely irreversible (unless the bed elevation is corrected).

General scour from a contraction usually occurs when the normal flow area of a stream is decreased either by a natural constriction or by a bridge. The contraction of the flow by the bridge can be caused by a decrease in flow area of the stream channel by the abutments projecting into the channel and/or the piers taking up a large portion of the flow area. Also, the contraction can be caused by approaches to the bridge which cut off the overland flow that normally goes across the floodplain during high flow. This latter case also can cause clear-water scour (defined further under Local Scour) at the bridge section because overland flow normally does not transport any significant bed material sediments. This clear-water picks up additional sediment from the bed when it returns to the bridge crossing. In addition, if floodwater returns to the stream channel at an abutment it increases the local scour there. A guide bank at an abutment decreases the risk from scour of that abutment from returning overbank flow. Also, relief bridges in the approaches reduce general scour by decreasing the amount of flow returning to the natural channel, which then decreases the scour problem.

Local Scour: This is the scour that occurs at a pier or abutment as the result of the pier or abutment obstructing the flow. This type of scour only occurs on a small portion of the channel width, where the obstructions to the flow cause local current accelerations creating vortices that remove the material around them.

If the transport rate of sediment away from the local region is greater than the transport rate into the region, a scour hole develops. As the depth of scour is increased, the strength of the vortex or vortices is reduced, the transport rate is reduced and equilibrium is reestablished and scouring ceases.

Generally, local scour depths are much larger than the other two. But, if there are major changes in stream conditions, such as a large dam built upstream or downstream of the bridge or severe straightening of the stream, long term bed elevation changes can be the larger element in the total scour.

Types of local scour are:

- » *Clear-water scour:* Clear-water scour occurs when there is no movement of the bed material of the stream upstream of the crossing but the acceleration of the flow and vortices created by the piers or abutments causes the material at their base to move.
- » *Live-bed scour:* Live-bed scour occurs when the bed material upstream of the crossing is also moving.

Lateral Stream Migration: In addition to the above, lateral shifting of the stream may also erode the approach roadway to a bridge and change the angle of the flow in the waterway at the bridge crossing, causing a change in the total scour.

Armoring: Armoring occurs on a stream or in a scour hole when the forces of the water during a particular flood are unable to move the larger sizes of the bed material. This protects the underlying material from movement. Scour around an abutment or pier may initially occur but as the scour hole deepens the coarsest bed material may move down in the hole and protect the bed so that the full scour potential is not reached.

Table 5.5 presents a checklist of potential problems relating to channel movement/scour and the causative factors which should be examined (see also Tables 6.8, 6.9, and 6.10 for the Design Checklists).

Table 5.5
Checklist of Potential Problems and Factors to be
Examined for Channel Movement and Scour

Potential Problem	Yes	No
Long term degradation or aggradation		
Reservoirs		
Mining		
Urbanization		
Watershed changes		
General scour		
Downstream variable water surface relationship		
Contraction and expansion		
Bed configuration and movement		
Live-bed scour		
Clear-water scour		
Bends		
Natural stream constriction		
Long approaches to the bridge over the floodplain		
Berms from sediment deposits		
Island or bar formations		
Debris		
Growth of vegetation in floodplain or channel		
Bed and sediment characteristics		
Armoring		
Lateral migration

Open Channels

6.1 Definition of Symbols

The following symbols will be used in equations throughout Chapter 6.

θ	=	The bank angle with the horizon
Φ	=	Angle of repose
Δy	=	Change in water surface elevation, ft
$\Sigma L_o/L_T$	=	Ratio of the summation of the distances between rows of buildings, L_o , to the total length of the reach along a profile parallel to flow, L_T , ft/ft
A	=	Cross section area of flow, ft ²
b	=	Channel bottom width, ft
C	=	Overall correction factor when using a different stability factor or specific gravity
C_{sf}	=	Stability factor correction factor
C_{sg}	=	Correction factor for specific gravity
D	=	Depth of flow, or hydraulic depth, ft
d_i	=	The average diameter of a rock particle for which "i" percent of gradation is finer by weight
E	=	Specific energy, ft
FB	=	Freeboard, ft
F_c	=	Section factor at critical depth, ft ^{3/2}
F_r	=	Froude number
g	=	Acceleration due to gravity, 32.2 ft/s ²
G	=	Gradation coefficient
h_v	=	Velocity head, ft
K_1	=	Bank angle correction factor
L_o	=	Individual length between buildings measured parallel to flow, ft
L_T	=	Total length of the floodplain, including buildings, ft
n	=	Manning's roughness coefficient (see Table 6-11)
n_o	=	Roughness coefficient for the area between the buildings in the floodplain (i.e., streets, yards, etc.)

n_u	=	Adjusted urban roughness coefficient
P	=	Wetted perimeter, ft
Q	=	Discharge, cfs
R	=	Hydraulic radius = A/P , ft
r_c	=	Radius of channel center-line curvature, ft
SF	=	Stability factor
S_o	=	Channel bottom slope, ft/ft
S_s	=	Specific gravity of the rock riprap
T	=	Channel width along the top of the water surface, ft
V	=	Average velocity of a section, ft/s
W_o	=	Clear width between buildings, measured perpendicular to flow, ft
W_T	=	Total width of the floodplain including buildings, ft
y	=	Distance from water surface to the centroid of the section, ft
Y	=	Depth of flow, ft
Y_c	=	Critical depth of flow, ft
Y_n	=	Normal depth of flow, ft

6.2 General

An open channel is a conveyance in which water flows with a free surface and may be natural or artificial. Natural streams usually consist of a normal or low flow channel and adjacent floodplains. For purposes of this guideline, the term open channel will include the total conveyance facility, floodplain, and stream channel.

Open channel hydraulics is of particular importance to design because of the interrelationship of channels to street and urbanization drainage. In the hydraulic analysis and design of bridges and culverts, open channel hydraulic principles are used to evaluate the effects of proposed structures on water surface profiles, flow and velocity distributions, lateral and vertical stability of the channel, stream regime, flood risk, and the potential reaction of channels to changes in variables such as urbanization; structure type, shape, and location; and scour control measures.

The hydraulic design process for open channels consists of establishing criteria, developing and evaluating alternatives, and selecting the alternative which best satisfies the established criteria. Elements that should be considered in the design process include capital investment and probable future costs, such as maintenance and flood damages to properties; traffic requirements; and impacts on the stream and floodplain environment.

If the proposed project will impact Waters of the U.S., the designer shall take into account requirements of the Clean Water Act (CWA), Section 404.

The Corps of Engineers, the permitting authority for the 404 permit, will require the designer to first avoid any impacts, second to limit impacts, and finally, to reduce impacts consistent with 404 b(1) Guidelines (National Archives and Records Administration, 1990). If the designer cannot avoid impacting Waters of the U.S., a requirement of the permit will be mitigation of impacted areas. The Corps of Engineers will also ensure compliance of the project with Section 401 of the Clean Water Act and will not issue a 404 permit without this certification. Section 401 of the Clean Water Act is the certification process by which the Arizona Department of Environmental Quality confirms that the federally permitted project meets state water quality standards.

Open channel design can be quite complex, requiring both specific education and extensive experience; however, when provided with specific procedures and criteria many urban applications can be successfully designed by engineers with substantially less experience. This chapter examines channel design for common urban applications, including roadside channels, channels within developments, and existing channels in urban areas or urbanizing areas that can be analyzed as "rigid". Occasionally, channel design of movable-bed and non-rigid channels will be required. These are complex, and specific design aids and descriptions of design are not included in this manual. For these applications, engineers qualified in open channel design should undertake the design. Checklists of the requirements and resources to be used for the more complex channel designs are included in Section 6.6.

6.2.1 Urban Open Channels

Urbanization causes an increase in both the volume and rate of stormwater runoff. The current practice in Maricopa County is to use storm sewers and open channels to convey stormwater to detention or, more commonly, retention facilities. This practice substantially reduces the impacts from urbanization; however, the volume of runoff carried by natural streams will usually be increased. The increase in the volume of runoff can cause a change in the overall stability of both natural and artificial channels. The analysis of these effects are outside the scope of this manual; however, a discussion of these effects is included in Section 6.6, as well as a checklist of technical matters to consider and a list of references which supports the checklist.

When land is developed, runoff from urban areas is concentrated to control stormwaters and provide a healthy environment. Even for small basins, concentrated runoff cannot simply be turned loose on adjacent grounds. Such action will result in erosion and the creation of a "new" urban channel; therefore, planning and design for urbanization needs to include approved disposal of newly created runoff from a development site. It is important to note that interfaces between natural and artificial channels are critical and require specific attention during design. In addition, sediment management and stream geomorphology are critical to both natural and artificial channels.

The preceding discussion simply illustrates a few requirements for design of urban channels. On larger scales, the designer may be faced with analysis or design of

“non-rigid” channels; however, many urban applications employ “rigid channel” design concepts in order to gain sufficient control of urbanized stormwaters, often within a limited right of way. This chapter addresses design of rigid channels.

6.2.2 Floodplains

Maricopa County has naturally occurring floodplains as well as those that have been created, or expanded, due to urbanization. Some of these floodplains have been identified and are being regulated by local municipalities, the Flood Control District, the Arizona Department of Water Resources (ADWR), and the Federal Emergency Management Agency (FEMA). The Flood Control District and most municipalities issue floodplain use permits for activities within FEMA designated floodplains, and drainage permits for activities located outside them. This system has evolved due to two separate statutory authorities resulting in two separate regulations. When developing projects in flood-prone areas be aware that even though the project is located in what a geomorphologist would classify as a floodplain, if it has not been mapped and published by FEMA, then—from a regulatory standpoint—it is not considered a floodplain. In that case, the developer would be required to obtain a drainage permit instead of a floodplain use permit.

Regulation of floodplains has been undertaken by authority contained in the National Flood Insurance Program. Engineers designing open channels or analyzing floodplains are faced with the provisions of the program; therefore, the following short description of the program and its requirements is included.

Special Flood Hazard Areas (SFHA) have been delineated on Flood Insurance Rate Maps (FIRMs) which can be obtained from the local jurisdictional agency (i.e., the Flood Control District of Maricopa County, City of Phoenix, etc.). The 100-year flood boundaries, flood insurance rate zones, and regulatory flood elevations are shown on the FIRMs. All new development and significant modifications to existing uses must be approved by the jurisdictional agency responsible for regulating floodplains in the channel reach in which the development or modifications are to occur.

6.3 Artificial Channels

Artificial open channels are used in drainage for a wide variety of applications. The applications vary in scale from modest roadside ditches and on-site drainage to large conveyance facilities that can be several hundred to several thousand feet wide. Channel linings heavily influence other physical characteristics of open channels.

This section covers the open channel design applications more commonly encountered

by civil engineers. The design methods presented in this section require rigid grade control of the channel.

Applications involving rivers and large washes or channels—which are considered “non-rigid”—require special design skills, and the design of these channels should not be attempted with the design techniques contained in this manual.

6.3.1 Route Considerations

Open channel failures frequently result from poor layout of surrounding land during the planning process. Without consideration of hydraulic parameters during the earliest phases of planning, unsafe conditions are likely to result and, often, facility and maintenance costs are excessive. A typical example of a safety problem is a high velocity channel being required in a residential area.

All natural channels are in a constant state of change. Natural channels that have small changes resulting from periods of low flows and periods of relatively high flows are considered in equilibrium. The ideal artificial channel is one that approximates a natural channel in equilibrium, or one which has been carved over a long period of time. These channels do not have excessive velocities, and are without closely-spaced, sharp, and reverse curvatures. Artificial channels should be aligned with the entrances and exits of hydraulic structures. In all cases, the issue of wet and dry weather safety should be a paramount consideration in route and right-of-way determinations.

Larger natural channels have low flow channels contained within their bottom width. To provide low cost maintenance, artificial channels should be stable for both low and high flow rates. This may require the use of a low flow channel to prevent the accumulation of silt, which reduces channel capacity. The route should permit the use of a uniform and stable channel side slope; permit the maintenance of subcritical flow; and maintain constant channel properties such as width, side slopes, and depth. Because this condition is sometimes difficult to achieve, it can result in channels that are likely to move and, hence, result in ongoing risk and continuous maintenance.

6.3.2 Choice of Channel

The choices of channel linings available to the designer are numerous, and depend upon good hydraulic practice, environmental design, sociologic impact, basic project requirements, recognition of risks involved, maintenance, and economics. However, from a practical standpoint, the basic choice to be made initially is whether or not the channel lining is concrete, soil cement, rock, or earth. In some instances, a grass lining is appropriate.

The actual choice must be made upon a variety of multi-disciplinary factors and complex considerations which include, among others:

Hydraulic

- Slope of thalweg
- Right-of-way configuration and amount required
- Stream bed controls—bed stability
- Capacity needed
- Basin sediment yield and channel transport capacity
- Topography
- Ability to drain adjacent lands
- Geotechnical
- Groundwater levels and groundwater recharge

Structural

- Costs
- Availability of material
- Areas for excavation materials (spoil sites)

Environmental

- Neighborhood character
- Neighborhood aesthetic requirements
- Need for new green areas
- Street and traffic pattern
- Municipal or Flood Control District policies/ordinances
- Need for open space

Sociological

- Neighborhood social patterns
- Neighborhood child population
- Pedestrian traffic
- Recreation needs

6.3.2.1 Description of Channel Types: Artificial channel types can vary with the shape of the section and with the lining used for the channel bottom and banks. Typical channel lining types include concrete, soil cement, rock, earth (natural), and grass. These linings can be used alone or in combination with other linings. Typical linings and sections are shown in Figure 6.1 and are discussed in detail in Section 6.5.

Some of the sections of Figure 6.1 show an optional low flow channel (discussed below), however, compound sections larger than a low flow channel may be desirable simply because they incorporate hiking trails and other recreational activities.

Concrete Lined Channels: Concrete lined channels are used primarily where right-of-

way is limited. The channels may be designed for either subcritical or supercritical flow and generally have steep side slopes because of the limited right-of-way. Inherently, these channels present greater personal safety problems both in wet and dry weather (see Section 6.3.2.4). In addition, supercritical flows present greater problems to the designer in the design of the channel and in the design of appurtenances such as bridges and culverts. Channels with supercritical flow require special attention to construction joint details, changes in channel alignment, transitions, and at the interface with all hydraulic structures.

Use of concrete lined channels is discouraged in residential and recreation areas. If concrete channels are needed in these areas, fencing should be used to control access.

Concrete lined channels require reinforcing steel and minimum concrete thicknesses dictated by anticipated structural loads and the clearance requirements of steel reinforcing. It is not recommended that non-reinforced concrete be used for open channels. In addition, concrete lined channels require weep holes and/or subdrains to prevent uplift damages. Figures 6.1 and 6.2 illustrate that the top of the concrete is tied into the ground, which is required to prevent erosion caused by water entering the channel laterally, eroding the soils behind the concrete and damaging the lining. Several instances of channel failure in the Maricopa County area have occurred due to the lack of a proper tie-in at the top of the concrete channel lining. Figure 6.2 provides details for key-ins required for concrete, shotcrete and soil cement channels.

Soil Cement: Soil cement linings are composed of a thick lining of soil cement without reinforcement and have been used successfully in Maricopa County. Soil cement is subject to weathering, including erosion, and may not have good life cycle traits when used in the bottom of channels. The side slopes can be steep (2 horizontal : 1 vertical); therefore, the same restrictions for concrete-lined channels should be placed on the use of soil cement channel types when they are used in residential and recreation areas.

With the possible exception of channel bottoms, soil cement can withstand higher velocities than some of the lining types. Soil cement is most likely to be used for a channel with a limited and restricted right-of-way or as bank lining near bridges and culverts where ambient stream velocities tend to be higher than the average velocity within a channel reach. If soil cement is to be used in conjunction with an earthen or grass-lined channel bottom, control of channel grade and scour must be incorporated into the design of the channel.

Rock Lined Channels: This class of lining includes both common riprap and gabion riprap linings. In general, both of these types require placement of a gravel-filter layer and/or filter fabric between the rock layer and the natural ground. Excluding applications for hydraulic structures, gabion riprap is normally used when rock of sufficient size for common riprap is unavailable, poorly shaped, and/or overly expensive for a project. Because of weathering and vandalism, gabion riprap should not be placed on slopes steeper than where common riprap would be used (see Section 6.5).

Riprap channels are to be designed for subcritical flow; however, because the

REINFORCED CONCRETE

VERTICAL WALL

EARTH OR GRASS

RIPRAP CHANNEL

Figure 6.1
Typical Channel Sections

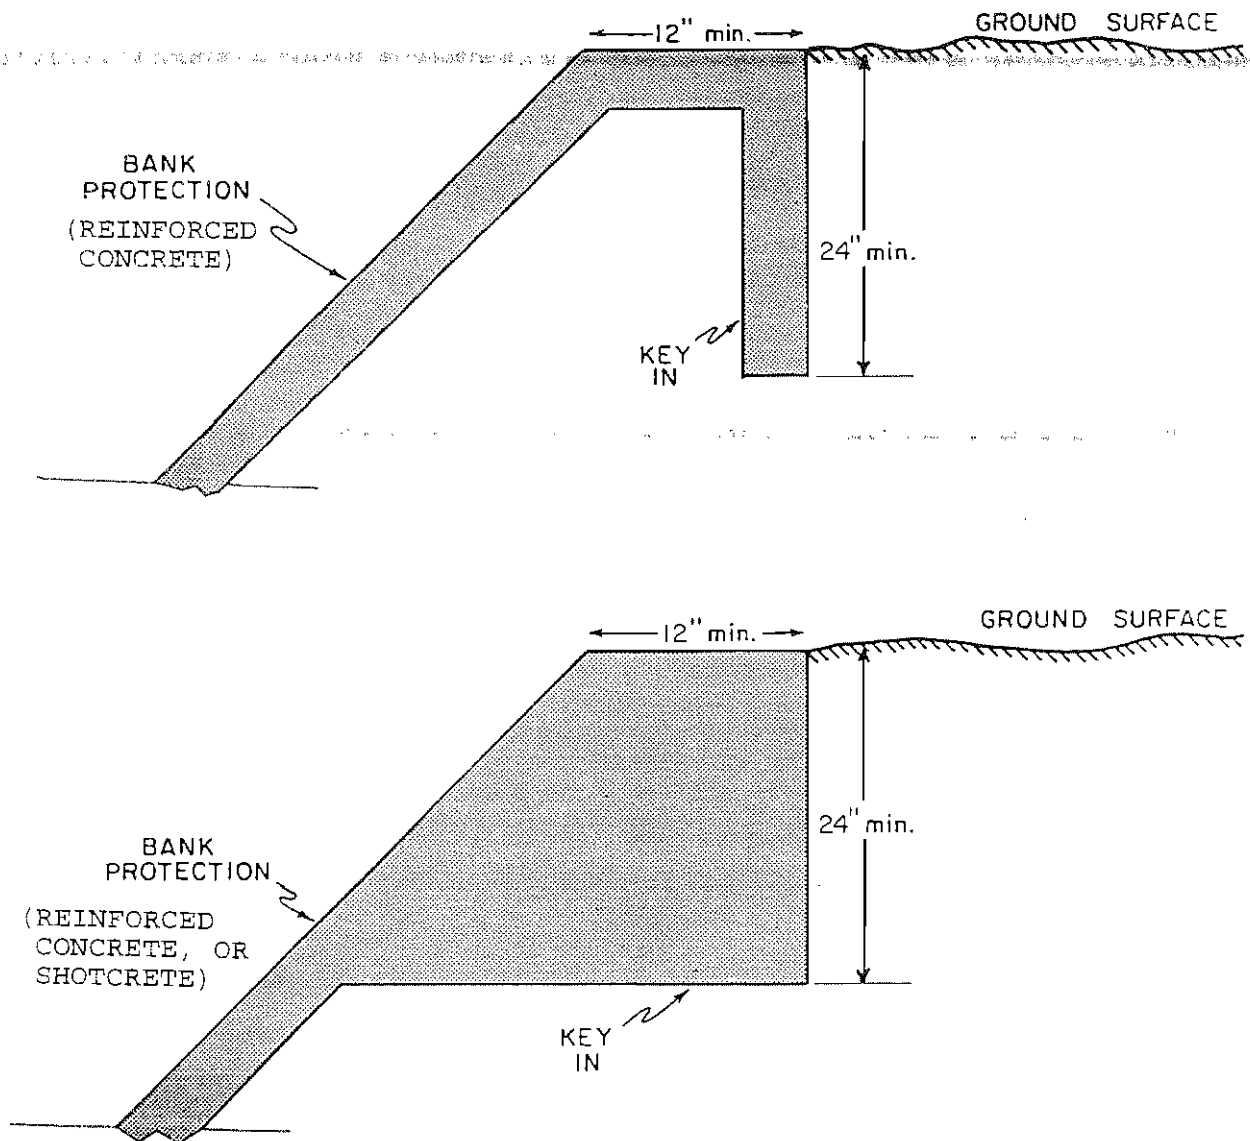

Figure 6.2
Typical Bank Protection Key-ins
(Simons, Li and Associates, 1988)

permissible side slopes are steeper (3 horizontal : 1 vertical) than allowed for either grass lined or earth lined channels, riprap lined channels will normally be used in areas with restricted right-of-way. These channels will flow in the subcritical range and the rough texture may permit an individual to exit from the channel during flows, potentially permitting less restrictive safety requirements than for a typical concrete-lined channel. Design around hydraulic structures may also be less restrictive. Use of toe rock with riprap side slopes can work successfully in combination with an earth bottom. This channel is much less prone to move than a totally earth lined channel. ~~Non-rigid design techniques must be used when earth channel bottoms are combined~~ with riprap sides. The riprap toe protection (toe rock) should be designed to protect against anticipated scour (see Figure 6.12).

Earth Lined Channels: This category includes both bare earth and naturally vegetated channels in Maricopa County. Subsequent to construction, some revegetation will naturally occur, or landscaping practices may be used to establish growth of indigenous plant materials. For Maricopa County, this growth will be desert-like, with few grasses and a sparse spacing of other plant materials.

Earth lined channels are designed for subcritical flow ranges. The width to depth ratios are large, the side slopes are flatter than 4 horizontal : 1 vertical, and grade control is a requirement of the design. The smaller-size range of these types of channels do not require low flow channels; however, for larger-sized channels and for channels used for pedestrian corridors, an armored low flow channel may be required to achieve effective, low-maintenance channels. Riprap toe protection may be used to increase channel stability.

Grass Lined Channels: These channels have similar properties to earth lined channels with side slopes no steeper than 4 horizontal : 1 vertical. The root structure of the grass permits higher flow velocities and smaller sections. Non-irrigated, grass lined channels will revert to earth lined channels; therefore, all references to grass lined channels will be for irrigated grass.

Because water must be conserved in the desert environment, grass lined channels are most likely to be used as part of landscaping for smaller development tracts and as part of local and regional park schemes where multiple use activities are included.

6.3.2.2. Flow Characteristics:

Design velocities for all linings should not fall below 2 fps to minimize sediment depositional problems.

Determine the maximum allowable velocity from Tables 6.1 and 6.2. Calculate the allowable capacity for the drainage ditch using Manning's formula with an appropriate n value. Manning's n values for typical channel materials are presented in Table 6.11 (page 6-64). If the natural channel slope would cause excessive velocity, employ drop structures, checks, riprap, or other suitable channel protection.

Table 6.1
Maximum Permissible Velocities for Roadside
Drainage Channels with Erodible Linings
 (USDOT, FHWA, 1961 and 1983)

Soils Type of Lining (Earth, No Vegetation)	Permissible Velocity ⁽¹⁾ , ft/s
Fine Sand (noncolloidal)	2.5
Sandy Loam (noncolloidal)	2.5
Silt Loam (noncolloidal)	3.0
Ordinary Firm Loam	3.5
Fine Gravel	5.0
Stiff Clay (very colloidal)	5.0
Graded, Loam to Cobbles (noncolloidal)	5.0
Graded, Silt to Cobbles (noncolloidal)	5.5
Alluvial Silts (noncolloidal)	3.5
Alluvial Silts (colloidal)	5.0
Coarse Gravel (noncolloidal)	6.0
Cobbles and Shingles	5.5
Shales and Hard Pans	6.0

- (1) For sinuous channels multiply permissible velocity by:
 0.95 for slightly sinuous;
 0.90 for moderately sinuous; and
 0.80 for highly sinuous

6.3.2.3 Low Flow Channels: The majority of storm events will be less than the design storm, resulting in frequent low flow conditions. Low flows in earth- or grass-lined trapezoidal channels will deposit sediment and develop their own pilot channel which will be meandering and could direct low flows into the channel banks causing bank erosion. Design of low flow channels will prevent meandering and will direct low flows in a controlled manner.

Rounding the channel bottom to approximate a parabolic shape will cause the centerline of the channel to act as a low flow channel. Alternatively, the channel bottom could be graded into a shallow V-shape to lower the centerline.

Because of the potential for long-term channel aggradation, base flows and crop irrigation return flows may require specific consideration. Waterways which are normally dry often have somewhat continuous low flows after urbanization because of

Table 6.2
Roadside Channels with Uniform Stand of
Various Grass Cover and Well Maintained ⁽¹⁾⁽²⁾
 (Adapted from USDOT, FHWA 1961 and 1983)

Cover	Slope Range, %	Permissible Velocity, fps	
		Erosion Resistant Soils	Easily Eroded Soils
Bermuda Grass	0 to 5	6.0	4.5
	5 to 10	5.5	4.0
	Over 10	5.0	3.0
Desert Salt Grass Vine Mesquite	0 to 5	5.0	4.0
	5 to 10	4.5	3.0
	Over 10	4.0	2.5
Lehman Lovegrass Big Galleta Purple Threeawn Sand Dropseed	0 to 5 ⁽³⁾	3.5	2.5
Sudangrass ⁽⁴⁾ Barley ⁽⁴⁾	0 to 5 ⁽³⁾	3.5	2.5

- (1) Use velocities over 5 fps only where good covers and proper maintenance can be obtained.
- (2) Grass is accepted only if an irrigation system is provided.
- (3) Not recommended for use on slopes steeper than 5 percent.
- (4) Annuals, used on mild slopes or as temporary protection until permanent covers are established.

lawn irrigation and other outside uses of water, including crop irrigation return flows for developments on the edge of urbanizing areas. Maricopa County is generally typified by low groundwater tables, porous surface materials and limited irrigation, which tend to reduce low flows and short-term problems of aggradation and wet channel bottoms.

Base flows for larger drainage basins can be a significant stability and maintenance problem for earth- or grass-bottomed channels. In this discussion, base flows can be considered as flow rates that are less than the 5- or 10-year storm events. If grass and earth channels are too wide, the low flows will tend to incise a channel within the bottom, giving rise to both higher maintenance requirements and more channel instability when larger storms occur. Because flows of sufficient size to cause a low flow channel to form may not occur for several years, the magnitude of this problem may not be observed for several years.

When calculations illustrate the need for low flow channels, it is important to provide for notches in hydraulic structures to pass low flows. Without this provision, the low flows will not be confined and local aggradation may lead to failure of hydraulic structures and channels.

6.3.2.4 Safety: Section 5.2.2.13 contains a full discussion of safety, however, with regard to open channels, it may be necessary to provide Category I safety devices—primarily fencing—to preclude wet and dry weather access to drainage facilities that can be hazardous.

Except as subsequently provided, fencing will be required for all new concrete, shotcrete, and soil cement lined channels with side-slopes steeper than 4:1 that meet a Class A hazard as defined in Table 5.2 (page 5-13). Subcritical channels lined with concrete, shotcrete, and soil cement lined depths and bottom widths less than 3 feet and 5 feet, respectively, will not require fencing. Fencing may be required by individual entities regardless of the conditions listed in this manual.

6.3.2.5 Maintenance: Maintenance considerations are an important factor in open channel design. Grass-lined channels require irrigation and mowing. Earth-lined channels need to be kept clear of vegetation and debris. Concrete-lined channels require periodic maintenance and may also require sediment removal after intense storms. Consider the required level of maintenance and obtain assurance of the proper level of maintenance for all designs.

6.3.3 Design of Artificial Channels

This manual provides the *Simplified Design Procedure* for normally encountered design problems in open channels that can be applied only to discharges less than 2,500 cfs. When a condition is encountered that is beyond the scope of this simplified procedure, an increase in the detail of analysis is required. Section 6.6 includes design checklists for artificial and natural channels. The basis of the checklists is for the designer to address the probable important factors on each assignment. For common, controlled conditions, there are simplified approaches to design that can be used; however, when a condition occurs that requires a higher level of technical approach, the design procedures require engineers qualified in open channel design techniques and more complex procedures.

The information contained in this section is to be used as the designer proceeds through the checklist items. As often noted in this manual, the intent is to provide design approaches and support for the most commonly encountered conditions. For more complex problems, a complete checklist and recommended minimum references to support the checklist are included in Section 6.6. These references are especially helpful for those facilities involving significant sediment transport issues or complex hydraulic structures for grade control and/or energy dissipation.

6.3.3.1 Design Criteria for the Simplified Design Procedure: This section addresses properties of channel cross sections. Methods of calculating channel bottom slope, hydraulic depths, and other hydraulic characteristics follow.

The parameters listed in Table 6.3 and within this section should be used as guideline values. The criteria in Table 6.3 *can* be adjusted, but only by making request to the Flood Control District and/or other regulating agency. The request must be accompanied by a specific detailed design prepared by a registered engineer using the long-form design procedure (checklist) outlined in Section 6.6. Conversely, in the course of design, conditions requiring more stringent criteria may be found. In this instance, use the more restrictive procedures and criteria. Table 6.3 contains the channel properties to be used by designers of open channels using the *Simplified Design Procedure*. It should be noted that the channel properties change with the design discharge, which is a result of the hydraulic characteristics of open channels. As the design discharge increases, rigid channel design becomes increasingly more difficult to achieve. Safety considerations and the force of water combine to demand greater and greater design skills as the design discharge increases.

6.3.3.2 Hydraulics of Open Channels: For a relatively long, straight, and uniform channel, normal depth (i.e., uniform flow) calculations can be used to determine the discharge capacity at varying depths for a constant cross-sectional area. However, practicing engineers working in an urban environment will rarely encounter either existing conditions or design conditions where uniform flow calculations are adequate to totally define the flow conditions associated with a given discharge. Transition sections, channel junctions or confluences, channel bends, and hydraulic structures (e.g., culverts and bridges) can create major or minor deviations from uniform flow conditions. Therefore, the engineer must consider these deviations (covered elsewhere in this manual) when designing or analyzing drainage channels.

Uniform Flow: For a given channel condition of roughness, discharge, and slope, there is only one possible depth for maintaining a uniform flow. This depth is the normal depth, Y_n . When roughness, depth and slope are known at a channel section, there can only be one discharge for maintaining a uniform flow through the section. This discharge is the normal discharge.

If the channel is uniform and resistance and gravity forces are in exact balance, the water surface will be parallel to the bottom of the channel. This is the condition of uniform flow; however, uniform flow is more often a theoretical abstraction than an actuality. The engineer must be aware that uniform flow computation provides only an approximation of what will occur; however, such computations are useful for planning.

The normal depth is computed so frequently that it is convenient to use special graphs for various types of cross sections to eliminate the need for time consuming trial and error solutions (see Figures 6.13 and 6.14, pages 6-65 and 6-66).

Equations 6.1 through 6.11 are presented to aid in determining fundamental quantities in open channel flow—such as normal and critical depth and specific energy and design

Table 6.3
Criteria for Using the Simplified Design Procedure
Artificial Channel Properties
Simplified Design Procedure
($Q < 2,500$ cfs)

Type of Channel Lining ⁽¹⁾	Side Slope, H:V	Maximum Velocity, fps ⁽²⁾
Concrete ⁽³⁾	Vertical ⁽⁴⁾	15
Soil Cement	2:1	9 ⁽⁵⁾
Grouted Rock	3:1	9 ⁽⁵⁾
Riprap	3:1	9 ⁽⁵⁾
Gabion Baskets	2:1	9 ⁽⁵⁾
Grass (irrigated & maintained)	4:1	2.5 to 6.0 ⁽⁶⁾
Earth	4:1	2.5 to 6.0 ⁽⁷⁾

- (1) The values in this table are for channel sections with the same lining material for bottom and sides. For conditions where the bottoms and sides of the channels are different, the most critical applicable criteria are to be used.
- (2) Maximum velocities listed for erodible linings are to be checked in each design to assure that erosion will not occur.
- (3) The concrete lining classification also includes mortar or concrete pneumatically applied (shotcrete) (see Section 6.5.2.7, page 6-36).
- (4) When using vertical sides, refer to Chapter 7 for design of reinforcement.
- (5) Guideline only. Strict limits have not been set because this manual recommends that these channels flow subcritically (see Critical Flow, page 6-16).
- (6) Refer to Table 6.2.
- (7) Refer to Table 6.1.

- Note:
1. Compute the Freeboard using Equation 6.10 (page 6-21), with minimums of 1 and 2 feet for channels designed for subcritical and supercritical flow, respectively. For curved channel sections, refer to Equation 6.9 (page 6-20).
 2. The criteria listed in this table are boundary values. The designer is responsible for determining adequacy of criteria for each specific application. For design of lining materials, analyses of soil conditions and subsurface drainage may be required by the Flood Control District and/or other jurisdictional agencies.

considerations of freeboard and minimum radius of curvature. See Section 6.1 for definitions of the symbols used in these equations.

Generally, it is necessary to apply Manning's Formula (Equation 6.1) to sections of the channel which have similar properties:

$$V = \left(\frac{1.49}{n}\right) R^{0.67} S_o^{0.5} \quad (6.1)$$

Multiplying velocity by the cross sectional area of flow results in:

$$Q = VA \quad (6.2)$$

Because of variable channel cross sections and channel properties, uniform flow computations are rarely used solely as the basis for open channel design. Normally, a designer will use these values for conceptual level decisions. Decisions relative to preliminary and final design requirements should be made through backwater determinations (see Section 6.4).

Critical Flow: Critical flow in an open channel or covered conduit with a free water surface is characterized by several conditions. Some of them are:

- The specific energy is a minimum for a given discharge.
- The discharge is a maximum for a given specific energy.
- The velocity head is equal to half the hydraulic depth in a channel of small slope.

$$h_v = \frac{V^2}{2g} = \frac{D}{2} \quad (6.3)$$

- The Froude number is equal to 1.0.

With the presence of a free surface in an open channel, the force of gravity has an effect on the state of flow. The effect of gravity on open channel flow is represented by the ratio of inertial forces to gravitational forces. This ratio is known as the Froude number (F_r) and is computed by rearranging Equation 6.3:

$$F_r = \frac{V}{(gD)^{0.5}} \quad (6.4)$$

For subcritical and supercritical flows $F_r < 1$ and $F_r > 1$, respectively.

The Froude number (F_r) will be used in this chapter as a design guideline. To avoid sediment deposition, velocities should not be below 2 fps.

Due to erosion and scour of erodible channels and safety concerns with excessively high velocities, the recommended upper limit of F_r is 2.0.

The specific energy (E) in open channels is the sum of the depth of flow and the velocity head:

$$E = Y + \frac{V^2}{2g} \quad (6.5)$$

A characteristic specific energy curve is made for a specific flow rate in a channel (see Figure 6.16, page 6-68). Two depths of flow, called alternate depths, will exist for each energy value; the lower depth will be supercritical and the higher depth will be subcritical. As the energy approaches a minimum, toward Y_c , the alternate depths will vary by small amounts. Minor changes in cross section, flow rate, channel roughness, or slope can cause the flow to pass through critical flow and on to its alternate depth—therefore, avoid the regime of flow near minimum specific energy. This flow phenomena is characterized by a wavy water surface, weak hydraulic jumps, and unsteadiness in the flow.

In the subcritical region, as F_r increases toward 1, the velocity increases and the depth of flow decreases. As long as the velocity does not increase past the permissible velocity shown in Table 6.3, short-lived instability of near critical flow is acceptable. On the other hand, near critical flows in the supercritical regime may cause hydraulic jumps with the minor changes in cross section, flow rate, channel roughness, or slope, as mentioned above. This type of flow instability is undesirable for any duration, therefore supercritical flow will be permitted only if the flow is well established in the supercritical flow regime.

The guidelines in this manual restrict soil cement, grouted rock, riprap, and grass and earth lined channels to subcritical flow.

The Froude Number limit for all types of channel linings is $F_r \leq 0.86$. For concrete, shotcrete, and mortar lined channels, the additional range of $1.13 \leq F_r \leq 2.0$ is allowed. So that flow will be stable, F_r should not fall between 0.86 and 1.13.

Since critical flow is to be avoided, it is important to be able to calculate the critical depth, Y_c . Substituting Q^2/A^2 for V^2 in Equation 6.3 yields:

$$\frac{Q^2}{g} = \frac{A^3}{T} \quad (6.6)$$

Equation 6.6 is solved by successive approximation, and will only be satisfied for critical flow for the given discharge and cross section. Manipulations of Equations 6.3 through 6.6 will yield simplified expressions to determine critical depth for common prismatic channels (see *Handbook of Hydraulics*, Brater and King, 1976). Only Equation 6.6 is included here because it is a general relation that will be satisfied for a channel of any cross section. The successful approximation of Y_c can be verified by checking whether the specific energy in Equation 6.5 has been minimized.

In applying Equation 6.6 and solving for F in Equation 6.4, if the depth is found to be at or near critical, the shape of the cross section or of the slope should be changed to achieve greater hydraulic stability.

To simplify the computation of critical flow, Figure 6.14 (page 6-66) gives dimensionless curves showing the relation between depth and the section factor, F_c , for rectangular, trapezoidal, and circular channels:

$$F_c = A(D)^{0.5} \quad (6.7)$$

Roughness Coefficients: Roughness coefficients (n) for use in Manning's equation vary considerably according to type of material, depth of flow, and quality of workmanship. Table 6.11 (page 6-64) lists roughness coefficients for pipes, earthen and natural channels and for various artificial channels.

If unsure of a specific value of roughness, the designer should check the possible range of roughness coefficients to locate potential problems.

6.3.3.3 Design of Rigid Channels: To be able to use the *Simplified Design Procedure*, the channel must be less than 2,500 cfs and "rigid." To be considered rigid, both the banks and the channel bottom must be stable. This generally results from the channel layout and from grade control.

Layout: In general, channel layout should follow existing washes, swales, or depressions.

Unless special exception is made by the governing agency, all artificial channels must begin and end where, historically, runoff has flowed.

This requirement applies both to the point where water becomes channelized and the point where runoff leaves the channel. This requirement is legal in nature as well as a matter of preventing erosion and property damage that would not have occurred without the drainage work being constructed. In addition, the water surface along the route *cannot* be raised so that damages occur as if improvements had not been made.

Care should be taken not to choose routes which lengthen the channel sufficiently to reduce channel slopes below that which will cause sediment deposition during low flows. Use Equations 6.1 and 6.2 to verify this condition. Likewise, channel layout can be used to reduce excessive channel slopes and the amount of grade control structures that are required.

It is most important to achieve a good channel layout in conceptual and preliminary layout of the surrounding land use. In general, the radius of curvature should not be less than three times the design flow top width.

Grade Control: There are many references to grade control requirements throughout this chapter, and it is difficult to overstate its importance. This section describes the benefits of grade control and the need for it in the design and assessment of channel stability. Actual design of man-made grade control structures is discussed in Chapter 7.

Grade control must be established as a condition of using the *Simplified Design Procedure*. It is a critical factor in the behavior of non-rigid channels. In its basic form, grade control can be any natural or man-made section of a channel that does not permit channel degradation or aggradation. Grade control is most often thought of as causing water to pass through critical depth; however, this condition is not required to establish grade control. Examples include: rock outcroppings, culverts under embankments, drop structures, and bridges; however, not all drop structures, culverts, or bridges can be considered as grade control structures. Channels with steep bottom slopes that cause channels to meander can wash out embankments, as can culverts and bridges plugged by debris or that are too small for the flood event that occurs.

Grade control and channel slope are interrelated. It does little good to establish grade control within a specific reach of open channel, when the channel downstream is headcutting or undergoing rapid deposition. When designing artificial channels, the designer needs to assess the stability of the section(s) immediately downstream from the segment under design. If there is evidence of ongoing downstream degradation, a grade control structure will be required—at a minimum—to a depth sufficient to preclude further headcutting in the channel.

Regardless of the size of watershed, a key design element, including conceptual layout, is establishing whether or not grade control exists below the design section. General degradation and aggradation is beyond the scope of this manual; however, references are provided at the end of this chapter.

For each alternative investigated, the selected channel slope should result in a stable channel, particularly for earth-lined channels. Within a reach of artificial channel, grade control structures should be used as required to meet the requirements listed in Table 6.3.

Channel Curvature:

For channels with Froude numbers less than 0.86, the ratio of the channel radius, r_c , (at the centerline) to the design width of the water surface shall be greater than 3.0.

Design of deflections and curves for supercritical flow is beyond the scope of this manual; refer to *Handbook of Hydraulics* (Brater and King, 1976) and *Open Channel Hydraulics* (Chow, 1959).

For Froude numbers greater than 0.86, the radius of curvature will be computed from the formula:

$$r_c \geq \frac{4V^2T}{gY} \quad (6.8)$$

Curves in a channel cause the maximum flow velocity to shift toward the outside of the bend. Along the outside of the curve, the depth of flow is at a maximum. This rise in the water surface is referred to as superelevation. The shift in the velocity may cause cross-waves to form, which will persist downstream when the flow is *supercritical*. Severe erosion, deposition and reduced channel performance result from severe curvatures in channel alignment. To minimize the effect due to channel bends, channel curvature should only be used where topographic or other conditions necessitate their use. If the flow is *supercritical*, special design criteria may need to be employed to eliminate the downstream effects.

For superelevation under subcritical conditions, the following formula is generally used:

$$\Delta y = \frac{V^2T}{gr_c} \quad (6.9)$$

The freeboard requirements are to be added to the superelevated water surface elevation for both subcritical and supercritical flow.

Freeboard:

Required freeboard is computed according to the following formula:

$$FB = 0.25\left(Y + \frac{V^2}{2g}\right) \quad (6.10)$$

The minimum freeboard value for rigid channels shall be 1 foot for subcritical and 2 feet for supercritical flows. Using a smaller freeboard in specific cases requires prior approval of the governing agency.

Additional freeboard may be called for in specific cases if aggradation is substantial during a single flow event.

Low Flow Channels: For channels with grass or earth bottoms, it is recommended that low flow channels (see Figure 6.1, page 6-8) be considered whenever the following condition exists:

$$\frac{b}{VY} \geq 1.40 \quad (6.11)$$

where V and Y are respectively, velocity and depth for the 100-year event.

The existence of frequent grade control structures may also preclude the requirement for compound channel sections; however, where grade control structures are used in conjunction with low flow channels, the hydraulic structure should be matched to pass flows within the low flow channel.

Supercritical Flow: Supercritical flow in an open channel in an urbanized area creates certain hazards which the designer must take into consideration. From a practical standpoint, it is generally unwise to have any curvature in a supercritical channel. Careful attention must be taken to insure against excessive oscillatory waves which may extend down the entire length of the channel from only minor obstructions upstream.

In a supercritical channel, there shall be no change of cross-sectional shape or area at bridges or culverts. Bridges or other structures crossing the channel must be anchored satisfactorily to withstand the full dynamic load which might be imposed upon the structure in the event of major trash plugging. Concrete linings must be protected from hydrostatic uplift forces which are often created by a high water table or momentary inflow behind the lining from localized flooding.

Backwater computation methods are applicable for computing the water surface profile or the energy gradient in channels having a supercritical flow; however, the computations must proceed in a downstream direction. The designer must take care to insure against the possibility of unanticipated hydraulic jumps forming in the channel.

Design of deflections and curves for supercritical flow is beyond the scope of this manual; refer to *Handbook of Hydraulics* (Brater and King, 1976) and *Open Channel Hydraulics* (Chow, 1959).

6.3.3.4 Preliminary Design: It is important that major design issues be identified and decisions about them made before proceeding into final design. In addition to the master plan consideration of the initial route, downstream control, and channel type, there are a number of technical items that must be evaluated prior to commencing final design. Some of these issues are:

- Control flow at the beginning and end of a channel reach to prevent damage to existing channels.
- Eliminate potential hydraulic jumps (this should only be an issue in concrete and shotcrete channels). Hydraulic jumps will be permitted only in planned locations at hydraulic structures (see Chapter 7).
- Minimize the use of alignment deflection in supercritical flow.
- The degree to which low flows affect channel stability and maintenance should be reflected in the chosen channel cross section.
- Determine safety requirements in conjunction with other hydraulic structures and with the inlets and outlets of conduits.
- Plan for possible secondary uses that can reduce urban costs by providing other benefits.
- Determine the need for freeboard requirements.

6.3.3.5 Final Design: Unless exempted by the governing agency, water surface profiles must be computed for all channels during final design and clearly shown on a copy of the final drawings. Computation of the water surface profile should use standard backwater methods, taking into consideration all losses due to changes in velocity, drops, bridge openings, and other obstructions (see Section 6.4). Other than supercritical concrete lined channels, computations begin at a known point and extend in an upstream direction for subcritical flow; this is why the channel should be designed from a downstream direction to an upstream direction. It is necessary to show the energy gradient on all preliminary drawings to help insure against errors. Whether or not the energy gradient line is shown on the final drawings is optional.

Remember that open channel flow in urban drainage is usually non-uniform because of bridge openings, curves, and structures, so backwater computations must be used for all final channel design work (see Section 6.4).

6.3.3.6 Design of Non-Rigid Channels: Large washes and locations where urbanized channels discharge into non-urbanized areas are the most likely candidates for this type of design. Non-rigid channel design requires special design skill and experience; therefore, design parameters and procedures are not described in this manual. However, a checklist for design requirements and a list of references that address non-rigid channel design are included in Section 6.6.

Non-rigid channel design can have economic benefits through reduced channel sections using movable beds and fixed sides, or permitting a channel to seek its own equilibrium without constructing drainage facilities. In these instances, designers may be required to develop calculations to prove channel stability or to prove that the channel will maintain its course within certain specified limits.

6.4 Natural Channels

In Maricopa County, floodplains tend to be wide, braided, and not permanently fixed in one location. Furthermore, velocities tend to be high, causing difficulties for channel modifications to be effective. Designers working in Maricopa County are, therefore, interested in the course of natural channels, especially where development will occur. Other design interests include the existing washes into which drainage from development will empty, and changes that occur in natural channels due to increases in the volume of runoff that occurs from urbanization.

Floodplain analysis tends to be very complex; however, a basic understanding of the behavior of natural channels and the methods of analysis can be very useful in the overall approach to drainage design. A common requirement for many projects is determining water surface profiles.

Natural channels tend to be in a steady state of change. Mountainous streams can be rigid, yet, in a geologic framework, are in a constant state of headcutting. While some mountainous regime channels exist, the natural channels that most commonly occur in Maricopa County lie within alluvial materials that have been deposited over long periods of time.

At transitions from natural to artificial channels, an array of problems can occur. Erosion can occur where the artificial channel has a substantial increase in conveyance compared to an upstream, natural channel. Because of their steep nature, the most common problem associated with mountainous streams is the sedimentation that predictably occurs where the natural channel interfaces with artificial channels which confine flows

through development. Low flow channel sections may be required in the artificial channels to move sediment. Sedimentation can be expected where attempts are made to sharply deflect the direction of flow from the naturally steep channels. This condition should be avoided.

In the more common alluvial cases, natural channels tend to deposit sediment and meander during low flow periods (which is most of the time) and to erode and straighten channel alignments during rare events. It is in this manner that the alluvial fans have been formed. Generally, if alluvial material exists, then there is some potential for the stream to reoccupy the alluvial areas resulting from a period of high flows. Therefore, it is necessary to acknowledge the potential for a natural channel to be 'non-rigid'.

Floodplain analyses tend to overlook this tendency for a natural channel to move, and, in many instances, this is an acceptable approach; however, the strict use of this approach within urbanized areas can lead to unfortunate results. As a result, there is often a need to utilize bank protection and hydraulic structures to selectively transform a non-rigid, natural channel into a more rigid channel.

Unless a natural channel is steadily aggrading or degrading, the construction of roads with adequately sized and protected bridges will significantly limit the lateral movement capability of most channels. Notable exceptions in Maricopa County are the extensive alluvial fan areas, which are outside the scope of this manual. Combined with bridges, the selective use of bank protection and grade control structures can prevent a natural channel from moving over a wide range of flow rates.

The entire hydrological approach to converting a natural waterway which has historically transported water from rural lands to an urban major drainage channel is so complex that applicable design criteria cannot be presented completely in this manual. It will suffice here to state that the planning for use of such channels must be undertaken with the full benefit of engineers with adequate experience in open channel flow, bed stability, and sediment transport, together with experts in related fields.

6.4.1 Analysis of Natural Channels

The investigations necessary to insure that a natural channel will be adequate are different for every waterway. Supercritical flow usually does not occur in natural channels and frequent checks should be made during the course of the backwater computations to insure that the computations do not reflect supercritical flow.

Because of the advantages which are available to a community by utilizing natural waterways for urban storm drainage purposes, the designer should consult with experts in related fields as to the methods of development. Where natural channels are used, the usual rules of freeboard depth, curvature, and other rules applicable to artificial channels do not apply. For instance, when laid out and developed for the purpose of being inundated during the major runoff peak, there can be significant advantages if the

designer incorporates into the planning the overtopping of the channel and localized flooding of adjacent areas. Using natural channels requires that primary attention be given to erosive tendencies and carrying capacity adequacy. The floodplain of the waterway must be defined so that adequate zoning can take place to protect the waterway from encroachment to maintain its capacity and storage potential.

Section 6.6 contains a checklist of technical issues that need to be addressed when analyzing waterways in the vicinity of bridges and culverts. A general approach for analyzing the effectiveness of natural channels include several tasks:

- Prepare cross sections of the channel for the major design runoff.
- Investigate the bed and bank material as to the particle size classification.
- Study the stability of the channel under future conditions of flow.
- Examine channel and overbank capacity to determine adequacy for 100-year runoff.
- Examine velocities in natural channels to verify that critical velocity is not exceeded for any section.
- Define water surface limits so that the floodplain can be zoned.
- Use roughness factors ("n" values) which are representative of non-maintained channel conditions.
- Divide the channel cross sections into units of similar properties for determination of water surface profiles.
- Specify the use of drops or check dams to control water surface profile slope, particularly for more frequently occurring storm runoff.
- Prepare plans and profiles of the floodplain. Make appropriate allowances for future bridges which will raise the water surface profile and cause the floodplain to be extended.
- Evaluate the freeboard with reference to proposed non-drainage structures.

Filling of the flood fringe reduces valuable storage capacity and tends to increase downstream runoff peaks. Filling should not be used in the urban waterways where hydrographs tend to rise and fall sharply.

6.4.1.1 Requirements for Natural Channels: Washes which traverse land designated for a proposed development may be left in their natural state provided that doing so would not be in conflict with an approved master drainage plan for the area—if one

exists—and provided that the development is adequately protected from flooding and erosion.

According to ARS 48-3609.A, during the course of the Master Planning process, the 100-year runoff will be used to delineate a floodplain for major channels with discharges of more than 500 cfs and will be processed through the local jurisdictional agency, ADWR, and FEMA.

One method of developing in the vicinity of a natural wash is to keep all structures out of its 100-year floodplain, as well as its attendant erosion-hazardous areas. Another possible method of developing in the vicinity of natural washes is to utilize part of the floodplain for development, while leaving the channel in its natural state. However, the approach would involve demonstrating that: 1) the encroachment would not adversely affect adjacent properties; and 2) the development would be located outside of any erosion-hazard areas which border the natural wash.

Encroachments into the floodplain of a natural water course are to be analyzed according to FEMA requirements.

The maximum rise in water surface shall not exceed those listed for the local regulating entity. As with all floodplain encroachments, the development must be adequately protected from flooding and erosion, and must not violate restrictions imposed by master drainage plans.

At no time should an encroachment adversely affect the stability of a water course or adversely alter flooding conditions on adjacent properties. When encroachment is proposed within the floodplain of a major watercourse, the regulating entity may, at its discretion, request that a detailed study be performed to determine if a reduction in overbank flood storage will significantly affect downstream flood peaks.

6.4.1.2 Applicable Methodologies:

Normal Depth and Velocity: If the depth and direction of the flow in an open channel are nearly constant (i.e., steady, uniform flow conditions), the flow regime is said to be “normal,” and the hydraulic characteristics of the channel can be evaluated by using the Manning's Equation (Equation 6.1).

When delineating natural floodplains using the Manning's equation, it is important to ensure that the energy grade line (EGL), slopes continuously in the downhill direction. The energy grade line is defined as a line connecting points of known total head or total specific energy, E , as computed by Equation 6.5.

In the cases where the slope of the energy grade line does not nearly equal the channel bed slope, it is not reasonable to use a uniform flow approach, and backwater calculations must be made.

Backwater Procedure: The previous section contained a brief discussion on computing normal depth, which assumes that changes in discharge, bed slope, and cross-sectional area and form, occur relatively gradually, however, sudden changes will produce additional turbulent energy losses which are not accounted for in the Manning's equation. This may be particularly true in cases of sudden contractions and expansions of the channel cross section.

In those instances where an upstream or downstream hydraulic control exists, the Standard Step Method should be used for evaluating water surface profiles. The procedure for making Standard Step calculations is given in several easily obtainable textbooks or references. An example form for the method is shown in Figure 6.15 (page 6-67). The designer can perform the Standard Step calculations using readily available and well-documented computer programs such as HEC-2 (USACE, 1990) or HEC-RAS (USACE, 1995a & b). These programs were developed by the U.S. Army Corps of Engineers and are distributed through several vendors.

One advantage of the Standard Step Method is that if the computation is started at an assumed elevation that is incorrect for the given discharge, the resulting flow profile will become more nearly correct with each succeeding cross section evaluated within a reach. If no accurate elevation is known within or near the reach under consideration, an arbitrary elevation may be assumed at a cross section far enough away from the "starting" cross section to correct for any initial error.

The step computations should be carried upstream if the flow is subcritical, and downstream if the flow is supercritical. Otherwise, step computations carried in the wrong direction tend to make the results diverge from the correct flow profile.

For natural streams flowing under supercritical conditions, critical depth should be used for determining the water surface profile. Velocities computed for the supercritical profile, however, should be used to evaluate the scour potential.

There are a large number of applications related to open channel flow in which the shape, or class of flow profiles are important to the designer. Figure 6.3 has been included as a reference to determine the type of flow profile that may exist in an artificial or natural channel.

6.4.1.3 Floodplain Widths and Depths in Channels with Composite Hydraulic Roughness: In the following sections, general analytical procedures are presented for evaluating floodplain hydraulics, with an emphasis on determining floodplain widths and flow depths in natural washes and constructed channels having non-uniform or composite hydraulic roughness.

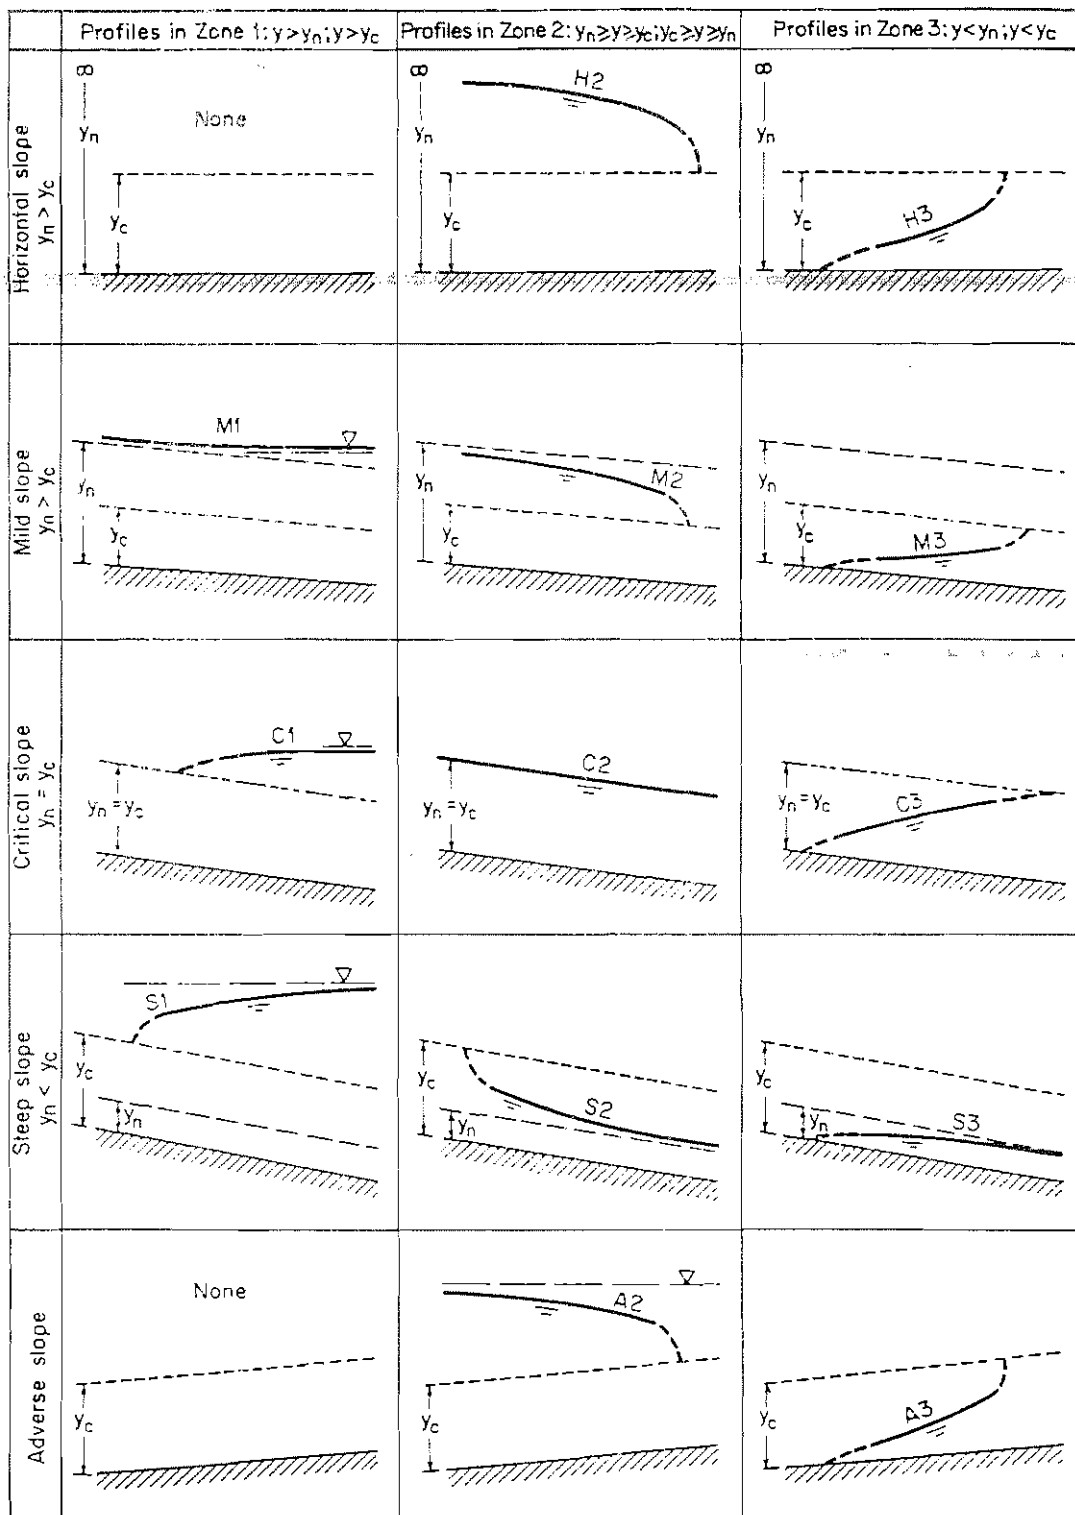

Figure 6.3
 Classification of Flow Portion of Gradually Varied Flow
 (Chow, 1959)

Composite Channels: The cross section of a watercourse or a street right-of-way may be composed of several distinct subsections, with each subsection having different hydraulic characteristics, such as hydraulic roughness and average flow depth. For example, an alluvial channel may have a primary, sand-bed channel which is bounded on both sides by densely-vegetated, overbank floodplains, or a flooded street section may be bounded on both sides by landscaped front yards having shallower flood depths and slower flow velocities.

In composite channels like these, the discharge is computed for each sub-section having distinct and different hydraulic characteristics, and the total computed discharge is set equal to the sum of the individual discharges. Similarly, the mean velocity for the entire flow cross section is assumed to be equal to the total discharge divided by the total water area. *Open-Channel Hydraulics* (Chow, 1959), provides an example of computing flow in channels having composite roughness.

Manning's Roughness Coefficients: Manning's roughness coefficients (see Table 6.11, page 6-64), for use in water surface profile calculations, should be carefully estimated by experienced engineers. The estimates should include consideration that roughness may vary with flood stage, depending on such factors as the width-depth ratio of the watercourse; presence of vegetation in the main channel and the overbank areas; the types of materials making up the channel bed; and the degree of meandering. Additional information concerning Manning's roughness coefficients can be found in Thomsen and Hjalmarson (1991), Davidian (1984), and Aldridge and Garret (1973).

In the urban setting, it is not unusual for buildings and other structures to occupy a significant portion of any given hydraulic cross section. Under these circumstances, it is often difficult to estimate both the effective width of the cross-section and the Manning's roughness coefficient for the overbank areas. When faced with such a situation, the engineer should eliminate the portion of the cross section occupied by the building.

Where only an estimate of the computed water surface elevation is needed, a second option may be selected: use the adjusted urban roughness coefficient, n_u , with the total cross-sectional area, (Hejl 1977). See Figure 6.4.

$$n_u = n_o \left(1.5 \left(\frac{W_T}{\Sigma W_o} \right) + \left(1 - \frac{W_T}{\Sigma W_o} \right) \frac{\Sigma L_o}{L_T} - 0.5 \right) \quad (6.12)$$

where all coefficients are as defined in Section 6.1.

6.4.1.4 Related Issues:

Maintenance: In many instances, specific maintenance access requirements are required by the local entity and/or the Flood Control District. In planning and designing open channels, the designer should determine these requirements at the outset of the project.

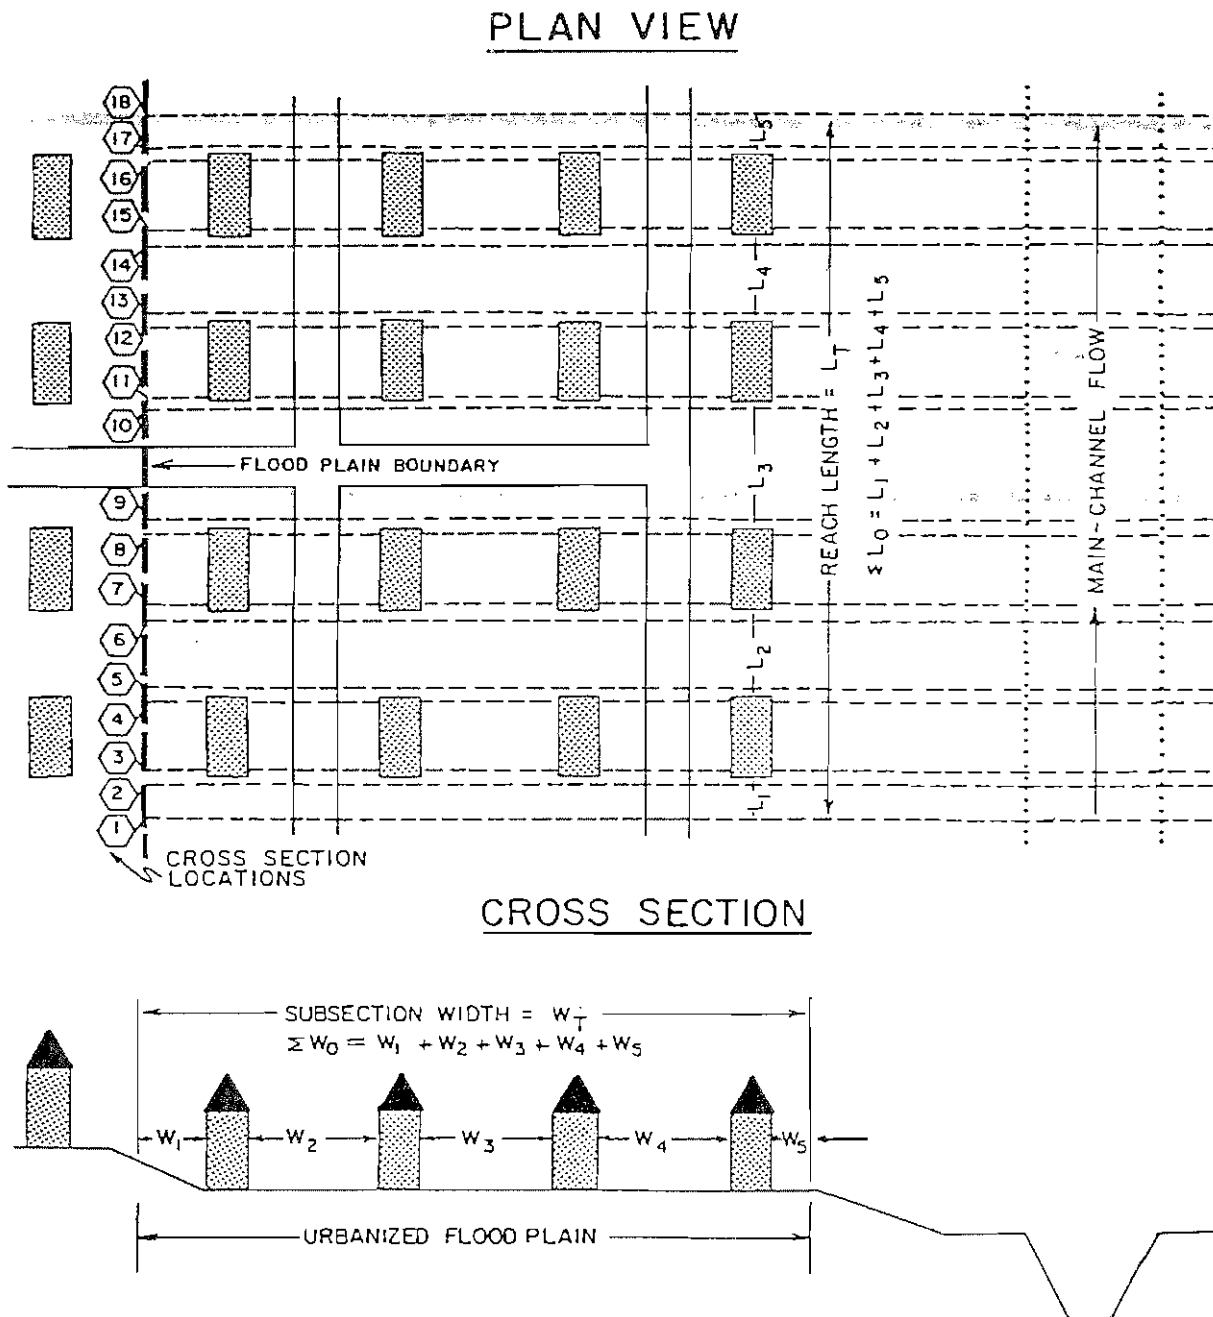

Figure 6.4
Diagram of Idealized Urban Floodplain
 (Hejl, 1977, Journal of Research, U.S. Geological Survey)

Development in Floodplains: Development in areas outside of the floodway in designated floodplains is permissible as long as floodplain and zoning regulations are met. The advance planning of developments that may be affected by the floodplain regulations requires a thorough understanding of floodplain regulations and drainage standards and may also require an engineering background in open channel hydraulics, river mechanics, and sediment transport.

6.5 Channel Linings

The type of channel lining which may be best suited for a particular purpose will depend upon a variety of factors, including hydraulic conditions, economic factors, soil conditions, material availability, aesthetics, and compatibility with existing improvements at the site. The following lining types are acceptable within their range of applicability.

6.5.1 Soil Cement

Soil cement has been shown to be an effective and economical method for slope protection and channel lining in the Maricopa County area.

6.5.1.1 Materials: A wide variety of soils can be used to make durable soil cement. For maximum economy and most efficient construction, it is recommended that:

1. The soil contain no material retained on a 3-inch (75 mm) sieve;
2. Between 40 percent and 80 percent pass the No. 4 (4.75 mm) sieve; and
3. Between 2 percent and 10 percent pass the No. 200 (0.074 mm) sieve.
4. The Plasticity Index (PI) of the fines should not exceed 10.

If the on-site material does not meet these guidelines, the addition of import material may be necessary. Standard laboratory tests are available to determine the required proportions of cement and moisture to produce durable soil cement. The design of most soil cement for water control projects is based on the cement content indicated by ASTM testing procedures and increased by a suitable factor to account for direct exposure, erosion or abrasion forces.

The Portland cement should comply with one of the following specifications: ASTM C150, CSA A5, or AASHTO M85 for Portland cement of the type specified; or ASTM C595 or AASHTO M240 for Portland blast-furnace slag or Portland pozzolan cement, excluding slag cements Types S and SA.

It is important that testing to establish required cement content be done with the specific cement type, soil, and water that will be used in the project.

Typically, soil cement linings are constructed by the central-plant method, where selected on-site soil materials, or soils borrowed from nearby areas, are mixed with Portland cement and water and transported to the site for placement and compaction.

6.5.1.2 Design of Soil Cement Linings: Figure 6.5 shows a composite channel consisting of an earth bottom with soil cement stabilization along the banks. On side slopes, the soil cement is often constructed by placing and compacting the material in horizontal layers stair-stepped up the slope. The rounded step facing results from ordinary placement and compaction methods. Generally an 8 to 8.5 foot minimum working width is required for placement and compaction of the soil cement layers by standard highway construction equipment. Figure 6.6 shows the relationship between slope of facing, thickness of compacted horizontal layer, horizontal layer width and minimum facing thickness measured normal to slope. For a horizontal working width of 8 feet, a side slope of 3:1 and 6-inch thick layers, the resulting minimum thickness of facing would be about 2 feet, measured normal to the slope.

An important consideration in the design of the soil cement facing is to ensure that all extremities of the facing are tied into non-erodible sections or abutments. The upstream and downstream ends of the facing should terminate smoothly into the natural channel banks. A buried cutoff wall normal to the slope or other measures may be necessary to prevent undermining of the soil cement facing by flood flows.

To protect against undermining of the soil cement layer by lateral inflows, the top of the lining should be keyed into the ground, as shown in Figure 6.2. As with any impervious channel lining system, seepage and related uplift forces should be considered and, if required, appropriate counter-measures provided, such as weep holes or subdrains. Tributary storm drain pipelines can normally be accommodated by placing and compacting the soil cement by hand, using small power tools, or by using a lean mix concrete. For earthen channels with soil cement side slope protection, the lining should be designed to extend to the anticipated depth of total scour.

6.5.2 Concrete Lined Channels

Reinforced concrete and shotcrete are alternative lining materials for channels with limited right of way and/or high velocity flow. The most common problems of concrete lined channels are due to bedding and liner failures. Typical failures are: 1) liner cracking due to settlement of the subgrade; 2) liner cracking due to the removal of bed and bank material by seepage force; and 3) liner cracking and floating due to hydrostatic back pressure from high groundwater.

Figure 6.5

Relationship of Slope, Facing Thickness, Layer Thickness, and
Horizontal Layer Width for Soil Cement Lining
 (Portland Cement Association, 1987)

Figure 6.7
 Flap Valve Installation for a Channel Underdrain
 (Simons, Li and Associates, 1981)

Lack of maintenance can result in vegetation growth through the concrete lining and sediment deposition in the channel which will increase the flow resistance. This reduction in channel capacity can cause overflow at design discharges and, consequently, permit the erosion of overbank material and failure of concrete lining.

6.5.2.1 Flow Regime Considerations: Concrete lined channels are usually designed for flow conditions where the Froude Number exceeds 1.13 and/or when velocities exceed five feet per second for earth lined channels. Froude Numbers for supercritical flow shall be greater than 1.13 and less than 2.0. Unstable flow conditions occur when the Froude number falls between 0.86 and 1.13 and must be avoided.

Supercritical flow in an open channel in an urbanized area creates certain hazards which the designer must take into consideration. From a practical standpoint it is generally unwise to have any curvature in a supercritical channel. Careful attention must be taken to prevent or control excessive oscillatory waves which may extend down the entire length of the channel from only minor obstructions upstream. Imperfections at joints may rapidly cause a deterioration of the joints, in which case a complete failure of the channel can readily occur. High velocity flow can enter cracks or joints and create uplift forces by the conversion of velocity head to pressure head causing damage to the channel lining. It is evident that when designing a lined channel with supercritical flow, the designer must use utmost care and consider all relevant factors.

All concrete lined channels must have continuous reinforcement extending both longitudinally and laterally. For channels carrying supercritical flow, there shall be no reduction in cross sectional area at bridges or culverts, or any obstructions in the flow path.

Bridges or other structures crossing the channel must be anchored satisfactorily to withstand the full dynamic load which might be imposed upon the structure in the event of major debris blockage. Tributary storm drain pipelines must not protrude into the channel flow area.

6.5.2.2 Lining Criteria: Generally, if slopes steeper than 2:1 are used, then safety and structural requirements become a primary concern. To determine the thickness of the lining refer to ADOT's *Urban Highways Channel Lining Design Guidelines*, February, 1989. Design of the lining should include consideration of anticipated vehicular loading from maintenance equipment. Joints in the lining should be designed in accordance with standard structural analysis procedures with consideration of the size of the channel, thickness of the lining and anticipated construction techniques. The concrete lining must be keyed into the adjacent overbanks as shown on Figure 6.2, page 6-9.

6.5.2.3 Roughness Coefficient: The roughness coefficient for a concrete lining can vary from 0.011 for a troweled finish to 0.020 for a very rough or unfinished surface. For shotcrete, roughness coefficients can vary from 0.016 to 0.025. The accumulation of sediment and debris must be taken into account when determining the roughness coefficient.

6.5.2.4 Bedding: Long-term stability of concrete lined channels depends in part on proper bedding. Undisturbed soils often are satisfactory for a foundation for lining without further treatment. Expansive clays are usually an extreme hazard to concrete lining and should be avoided. A filter underneath the lining is recommended to protect fine material from creeping along the lining. A well-graded gravel filter should be placed over the channel bed prior to channel lining with concrete.

6.5.2.5 Transitions: Since concrete-lined channels are often used at locations where excessive seepage exists or smaller channel cross sections are required, transitions will be required both upstream and downstream of the concrete lined channel to ensure control of flood flows, prevent undermining of the lining and reduce turbulence. Transitions should be lined with concrete or riprap to reduce scour potential.

Cutoff walls should be incorporated with transitions at both the upstream and downstream end of the concrete lined channel to reduce seepage forces and prevent lining failure due to scour, undermining, and piping. The depth of cutoff walls should extend below the expected scour depth. Determination of expected total scour depth requires specialized analyses that are beyond the scope of this manual. References are listed at the end of this chapter.

6.5.2.6 Underdrainage: The probability of damaging the concrete lining due to hydrostatic back pressure and subgrade erosion can be greatly reduced by providing underdrains. There are two types of artificial drainage installations. One type consists of 4- or 6-inch diameter perforated pipelines placed in gravel-filled trenches along one or both toes of the inside slopes. These longitudinal drains are either connected to transverse cross drains which discharge the water below the channel or to pump pits, or extend through the lining and connect to outlet boxes on the floor of the channel. The outlet boxes are equipped with one-way flap valves which prevent backflow and relieve any external pressure that is greater than the water pressure on the upper surface of the channel bottom. The second type consists of a permeable gravel blanket of selected material or sand and gravel pockets, drained into the channel at frequent intervals (10 to 20 feet) by flap valves in the channel invert. Figure 6.7 shows a drawing of a flap valve for use without tile pipe and in a fine gravel and sand subgrade. Both the tile and pipe system and the unconnected flap valve type must be encased in a filter that will prevent piping of subgrade material into the pipe or through the valve. For detailed underdrains refer to *Lining for Irrigation Canals* (USBR, undated).

Where a lesser degree of seepage control is warranted, weep holes spaced at appropriate intervals may be used. When embankment safety may be compromised or when ground levels may be raised by draining from the lined channel, weep holes may be equipped with flap valves or other measures that allow seepage relief but prevent backflow or introduction of surface water behind the lining.

6.5.2.7 Shotcrete: The shotcrete process has become an important and widely used technique. Shotcrete is mortar or concrete pneumatically projected at high velocities

onto a surface. In the past, the term 'gunite' was commonly used to designate dry-mix mortar shotcrete. The term is currently outdated and 'shotcrete' has become the trade name for all pneumatically applied dry-mix or wet-mix concrete or mortar.

ACI 506R (1985) discusses the properties, applications, materials, reinforcement, equipment, shotcrete crews, proportioning, batching, placement, and quality control of the shotcrete process.

As a channel lining, shotcrete is an acceptable method of applying concrete with a general improvement in density, bonding, and decreased permeability. The same design considerations discussed in Sections 6.5.2.1 to 6.5.2.6 apply in the design of shotcrete channels.

6.5.3 Riprap Lined Channels

Graded riprap can be an effective lining material if properly designed and constructed. The choice of riprap usually depends on the availability of graded rock with suitable material properties and at a cost that is competitive with alternative lining systems.

Riprap design involves the evaluation of five performance areas. These areas include the evaluation of:

- riprap quality;
- riprap layer characteristics;
- hydraulic requirements;
- site conditions; and
- river conditions.

In Arizona, site requirements and river conditions are important factors in the protection of bridge structures and flood control channels.

6.5.3.1 Riprap Quality: Riprap quality determination refers to the physical characteristics of the rock particles that make up the bank protection. Qualities determined to be most important include density, durability, and shape. Requirements for each of these properties are summarized in this section.

Specific Gravity (Density): The design stone size for a channel depends on the particle weight, which is a function of the density or specific gravity of the rock material. A typical value of specific gravity in Maricopa County is 2.4. All stones composing the riprap should have a specific gravity equal to or exceeding 2.4, following the standard test ASTM C127.

Durability: Durability addresses the in-place performance of the individual rock particles, and also the transportation of riprap to the construction site. In-place

deterioration of rock particles can occur due to cycles of freezing and thawing, or can occur during transportation to the site. The rock particles must have sufficient strength to withstand abrasive action without reducing the gradation below specified limits. Qualitatively, a stone that is hard, dense, and resistant to weathering and water action should be used. Rocks derived from igneous and metamorphic sources provide the most durable riprap.

Laboratory tests should be conducted to document the quality of the rock. Specified tests that should be used to determine durability include the durability index test and absorption test (see ASTM C127). Based on these tests, the durability absorption ratio (DAR) is computed as follows:

$$DAR = \frac{\text{Durability Index}}{\text{Percent Absorption} + 1} \quad (6.13)$$

The following specifications are used to accept or reject material:

1. DAR greater than 23, material is accepted;
2. DAR less than 10, material is rejected;
3. DAR 10 through 23:
 - a. Durability index 52 or greater, material is accepted; and,
 - b. Durability index 51 or less, material is rejected.

Shape: There are two basic shape criteria. First, the stones should be angular. Second, not more than 25 percent of the stones should have a length more than 2.5 times the breadth. The length is the longest axis through the stone, and the breadth is the shortest axis perpendicular to the length. Angularity is a qualitative parameter which is assessed by visual inspection. No standard tests are used to evaluate this specification.

6.5.3.2 Riprap Layer Characteristics: The major characteristics of the riprap layer include: characteristic size; gradation; thickness; and filter-blanket requirements.

Characteristic Size: The characteristic size in a riprap gradation is the d_{50} . This size represents the average diameter of a rock particle for which 50 percent of the gradation is finer, by weight.

Gradation: To form an interlocked mass of stones, a range of stone sizes must be specified. The object is to obtain a dense, uniform mass of durable, angular stones with no apparent voids or pockets. The recommended maximum stone size is 2 times the d_{50} and the recommended minimum size is one-third of the d_{50} .

Table 6.4
Riprap Gradation Limits
(USDOT, FHWA, HEC-11)

Stone Size Range	Stone Weight Range	Percent of Gradation
1.5 d_{50} to 1.7 d_{50}	3.0 W_{50} to 5.0 W_{50}	100
1.2 d_{50} to 1.4 d_{50}	2.0 W_{50} to 2.75 W_{50}	85
1.0 d_{50} to 1.15 d_{50}	1.0 W_{50} to 1.5 W_{50}	50
0.4 d_{50} to 0.6 d_{50}	0.1 W_{50} to 0.2 W_{50}	15

The gradation coefficient, G , should equal 1.5.

$$G = 0.5(d_{84}/d_{50} + d_{50}/d_{16}) \quad (6.14)$$

Table 6.4 provides design gradations for riprap. As a practical matter, the designer should check with local quarries and suppliers regarding the classes and quality of riprap available near the site.

Thickness: The riprap-layer thickness shall be the greater of 1.0 times the d_{100} value, or 1.5 times the d_{50} value. But the thickness need not exceed twice the d_{100} value. The thickness is measured perpendicular to the slope upon which the riprap is placed.

Filter Blanket Requirements: The purpose of granular filter blankets underlying riprap is two-fold. First, they protect the underlying soil from washing out; and, second, they provide a base on which the riprap will rest. The need for a filter blanket is a function of particle-size ratios between the riprap and the underlying soil which comprise the channel bank. The inequalities that must be satisfied are as follows:

$$\frac{(d_{15})_{filter}}{(d_{85})_{base}} < 5 < \frac{(d_{15})_{filter}}{(d_{15})_{base}} < 40 \quad (6.15a)$$

$$\frac{(d_{50})_{filter}}{(d_{50})_{base}} < 40 \quad (6.15b)$$

In these relationships, “filter” refers to the overlying material and “base” refers to the underlying material. The relationships must hold between the filter blanket and base material and between the riprap and filter blanket (USDOT, FHWA, HEC-15, 1988).

If the inequalities are satisfied by the riprap itself, then no filter blanket is required. If the difference between the base material and the riprap gradations are very large, then multiple filter layers may be necessary. To simplify the use of a gravel filter layer, Table 6.5 outlines recommended standard gradations.

The Type-I and Type-II bedding specifications shown in Table 6.5 were developed using the criteria given in Equations 6.15a and 6.15b, considering that very fine grained, silty, non-cohesive soils can be protected with the same bedding gradation developed for a mean grain size of 0.045 mm. The Type-I bedding in Table 6.5 is designed to be the lower layer in a two-layer filter for protecting fine grained soils. When the channel is excavated in coarse sand and gravel (i.e., 50 percent or more by weight retained on the No. 40 sieve), only the Type-II filter is required. Otherwise, two bedding layers (Type-I topped by Type-II) are required. For the required bedding thickness, see Table 6.6.

Filter Fabric Requirements: The design criteria for filter fabric are a function of the permeability of the fabric and the effective opening size. The permeability of the fabric must exceed the permeability of the underlying soil, and the apparent opening size (AOS) must be small enough to retain the soil.

The criteria for apparent opening size are as follows:

1. For soil with less than 50 percent of the particles, by weight, passing a No. 200 sieve, the AOS should be less than 0.6 mm (a No. 30 sieve).
2. For soil with more than 50 percent of the particles, by weight, passing a No. 200 sieve, the AOS should be less than 0.3 mm (a No. 50 sieve).

Filter fabric is not a complete substitute for granular bedding. Filter fabric provides filtering action only perpendicular to the fabric and has only a single equivalent pore opening between the channel bed and the riprap. Filter fabric has a relatively smooth surface which provides less resistance to stone movement. Tears in the fabric greatly reduce its effectiveness so that direct dumping of riprap on the filter fabric is not allowed and due care must be exercised during construction. The site conditions and specific application and installation procedures must be carefully considered in evaluating filter fabric as a replacement for granular bedding material. Filter fabric can provide an adequate bedding for channel linings along uniform mild sloping channels where leaching forces are primarily perpendicular to the fabric.

Numerous failures have occurred because of the improper installation of filter fabric. Therefore, when using filter fabric it is critical that the manufacture's guidelines for installing it be followed.

Table 6.5
Gradation for Gravel Bedding
(Simons, Li and Associates, 1989)

Standard Sieve Size	Type I ⁽¹⁾	Type II ⁽¹⁾
3 inches	-	90 to 100
1-1/2 inches	-	-
3/4 inch	-	20 to 90
3/8 inch	100	-
#4 (4.75 mm)	95 to 100	0 to 20
#16 (1.18 mm)	45 to 80	-
#50 (0.30 mm)	10 to 30	-
#100 (0.15 mm)	2 to 10	-
#200 (0.075 mm)	0 to 2	0 to 3

(1) Percent passing by weight

Thickness Requirements for Gravel Bedding

Riprap Classification	Minimum Bedding Thickness, inches		
	Fine Grain Native Soils		Coarse Grain Native Soils
	Type I	Type II	Type III
6", 8"	4	4	6
12"	4	4	6
18"	4	6	8
24"	4	6	8
30"	4	8	10
36"	4	8	10

6.5.3.3 Hydraulic Design Requirements:

General: Channel linings constructed of placed, graded riprap or wire enclosed rock to control channel erosion have been found to be cost effective where channel reaches are relatively short (0.25 mile or less) and where a nearby source of quality rock is available.

Situations where riprap or wire enclosed rock (gabion basket) linings may be appropriate are:

1. Major flows are found to produce channel velocities in excess of allowable non-eroding values;
2. Channel side slopes at 3:1 for riprap and 2:1 for enclosed rock linings; and
3. Where rapid changes in channel geometry occur, such as channel bends and transitions.

This section presents design requirements for graded riprap, while Section 6.5.5 contains additional design considerations specifically related to wire enclosed rock. Both Sections are valid only for subcritical flow conditions where the Froude Number is 0.86 or less.

Riprap Sizing: Several reference sources are available for design procedures. Two recommended sources are:

1. Design of Riprap Revetment (Federal Highway Administration, Hydraulic Engineering Circular No. 11, Publication No. FHWA-IP-89-016, March 1989)
2. Hydraulic Design of Flood Control Channels (Corps of Engineers, EM-1110-2-1601, 1991)

The riprap sizing method presented here is from HEC-11, for a complete discussion on this method the designer is referred to the original source of this method. This method is based on tractive force (shear stress) theory but with velocity as its primary design parameter. This is a blend between the two approaches of permissible velocity and permissible tractive force. The hydraulic assumptions are uniform, steady, subcritical flow. However, adjustments to the design equation are provided for other regimes and conditions such as gradually varying flow and approaching rapidly varying flow. In this method, the riprap size is selected such that the flow induced tractive force does not exceed the critical shear stress of the riprap. The critical shear is based on Shields' relationship, a function of specific weight of water, specific weight of the riprap material, the median rock size (d_{50}), Shields parameter, and a factor that is a function of the bank angle and riprap's material angle of repose. The average shear stress or tractive force exerted by flowing water is the product of unit weight of water, energy grade line slope and hydraulic radius. These two equations are combined to develop the design tractive force relationship in terms of a stability factor (SF). The stability factor is

defined as the ratio of the average tractive force exerted by the flow field and the riprap materials critical shear stress. Therefore if the stability factor is greater than 1.0, the critical shear stress is greater than the flow induced tractive stress and the riprap is considered stable.

For the HEC-11 method the d_{50} (ft) is determined by:

$$d_{50} = \frac{0.001 V_a^3}{D_{avg}^{0.5} K_1^{1.5}} \quad (6.16)$$

Where V_a (ft/s) is the average velocity in the main channel, D_{avg} (ft) is the average flow depth in the main channel, and K_1 is the bank angle correction factor. The bank angle correction factor is determined using equation 6.17.

$$K_1 = \left[1 - \frac{\sin^2 \theta}{\sin^2 \Phi} \right]^{0.5} \quad (6.17)$$

Where θ is the bank angle with the horizontal, Φ is the riprap material's angle of repose. The bank angle correction factor can also be determined using Figure 6-9. The riprap material's angle of repose can be determined using Figure 6-8.

Equations 6.16 is based on a rock riprap specific gravity of 2.65, and a stability factor of 1.2. Equations 6.18 and 6.19 present correction factors for other specific gravities and stability factors.

$$C_{sg} = \frac{2.12}{(S_s - 1)^{1.5}} \quad (6.18)$$

Where S_s is the specific gravity of the rock riprap

$$C_{sf} = \left(\frac{SF}{1.2} \right)^{1.5} \quad (6.19)$$

Where SF is the stability factor to be applied. Table 6.7 presents guidelines for the selection of an appropriate value for the stability factor.

The correction factors computed using equations 6.17 and 6.18 are multiplied together to form a single correction factor C. This correction factor is then multiplied by the

riprap size computed from equation 6.16 to arrive at a stable riprap size.

The stability factor is used to reflect the uncertainty in the hydraulic conditions at a particular site. Equation 6.16 is based on the assumption of uniform or gradually varying flow. In many instances, this assumption is violated or other uncertainties come to bear. For example, debris and/or ice impacts, or the cumulative effect of high shear stresses and forces from wind and/or boat generated waves. The stability factor is used to increase the design rock size when these conditions must be considered. Table 6.7 presents guidelines for the selection of an appropriate value for the stability factor.

The minimum thickness of riprap linings shall be the greater of 1.0 times d_{100} or 1.5 times d_{50} .

Table 6.7
Stability Factors
(USDOT, FHWA, HEC-11, 1989)

Condition	Stability Factor Range
Uniform Flow: Straight or mildly curving reach (curve radius/channel width > 30); Impact from wave action and floating debris is minimal; Little or no uncertainty in design parameters.	1.0 - 1.2
Gradually Varying Flow: Moderate bend curvature (30 > curve radius/channel width > 10); Impact from wave action and floating debris is moderate.	1.3 - 1.6
Approaching rapidly varying flow: Sharp bend curvature (10 > curve radius/channel width); Significant impact potential from floating debris and/or ice; Significant wind and/or boat generated waves (1-2 ft); High flow turbulence; Turbulently mixing flow at bridge abutments; Significant uncertainty in design parameters.	1.6 - 2.0

Example $D_{50}=1.0$ ft.; Angular Riprap
 $\phi=41^\circ$

Bank Angle Correction Factor, K_1
(USDOT, FHWA, HEC-11, 1989)

6.5.4 Grouted Rock

6.5.4.1 General: Grouted rock is a structural lining comprised of a blanket of rock that is interlocked and bound together by means of concrete grout injected into the void spaces to form a monolithic revetment. The grout must extend the full thickness of the rock blanket. ~~With the face rocks exposed for a maximum of one-fourth to one-third of their depth.~~

Grouted rock provides a stable lining similar to concrete with the added advantage of a higher roughness factor due to the rock surfaces projecting above the grout layer. However, it is a rigid revetment that does not conform to changes in bank geometry due to settlement, and is susceptible to failure from undermining and the subsequent loss of the supporting bank material.

6.5.4.2 Materials:

Rock: Rock for grouting should conform to the property requirements described in Section 6.5.3.1. Graded riprap should not be used for grouting, as the smaller rock in a graded mix occupies the void spaces to be filled with grout. Figure 6.10 illustrates the relationship between the design velocity and the required riprap blanket thickness for grouted rock designs. The median rock size should not exceed 0.67 times the blanket thickness and the largest rock used should not exceed the blanket thickness. A class of riprap from Table 6.5 may be specified, with the requirement that rock smaller than the d_{50} size be removed. Additional details on grouted rock may be found in Chapter 7.

Grout: The grout mix should be specified to provide the strength and durability required to meet the specific application. The minimum 28-day compressive strength shall be 2,000 psi and the slump shall be within a range of 4 to 7 inches. The stone aggregate should conform to the gradation requirements of Size Number 8 course aggregate (3/8 inch to No. 8) as specified in ASTM C-33. A maximum of 30 percent of the cementous material may be fly ash (ASTM C-618, Type C or F). Fiber reinforcement may be added to the grout to provide additional control of shrinkage and cracking.

6.5.4.3. Design Considerations: Since grouted rock is a structural lining similar to reinforced concrete, it is subject to the same design considerations. Rock must be sized for the anticipated hydraulic design conditions. Foundation conditions must be evaluated and provisions made for underdrainage and seepage control. If only bank protection is to be provided, the grouted rock protection must extend below the channel invert to a depth below the estimated depth of total scour. Determination of estimated depth of total scour requires specialized analyses that are beyond the scope of this manual. References are listed at the end of this chapter. For more detailed analysis of grouted rock, refer to FHWA's HEC-11.

Figure 6.10
Required Blanket Thickness of Grouted Rock
 (USDOT, FHWA, HEC-11, 1989)

6.5.5 Wire Enclosed Rock (Gabion Baskets)

6.5.5.1 General: Wire enclosed rock refers to rocks that are confined by a wire basket so that they act as a single unit. The wire mesh enclosed rock units are also known as gabion baskets or gabion mattresses. One of the major advantages of wire enclosed rock is that it provides an alternative in situations where available rock sizes are too small for ordinary riprap. Another advantage is the versatility that results from the regular geometric shapes of wire enclosed rock. The rectangular blocks and mats can be fashioned into almost any shape that can be formed with concrete. The durability of wire enclosed rock is generally limited by the service life of the galvanized binding wire which, under normal conditions, is considered to be about 15 years. Water carrying silt, sand or gravel can reduce the service life of the wire. Also, water which rolls or otherwise inoves cobbles and large stones breaks the wire with a hammer and anvil action and considerably shortens the life of the wire. The wire has been found to be susceptible to corrosion by various chemical agents and is particularly affected by high

sulfate soils. If corrosive agents are known to be in the water or soil, a plastic coated wire should be specified.

Wire enclosed rock is not maintenance free and must be periodically inspected to determine whether the wire is sound. If breaks are found while they are still relatively small, they may be patched by weaving new strands of wire into the wire cage. Wire enclosed rock installations have been found to attract vandalism. Flat mattress surfaces seem to be particularly susceptible to having wires cut and stones removed. It is recommended that, where possible, mattress surfaces be buried, where they are less prone to vandalism. Wire enclosed rock installations should be inspected at least once a year under the best circumstances and may require inspection every three months in vandalism prone areas in conjunction with a regular maintenance program. Mattresses on sloping surfaces must be securely anchored to the surface of the soil as discussed in Section 6.5.5.3.

6.5.5.2 Materials:

Rock and Wire Enclosure Requirements: Rock filler for the wire baskets should meet the rock property requirements for ordinary riprap. Rock sizes and basket characteristics should meet the manufacturer's specifications.

Bedding Requirements: Long term stability of riprap and gabion erosion protection is strongly influenced by proper bedding conditions. A large percentage of all riprap failures are directly attributable to bedding failures, which is particularly disturbing in light of the fact that over half of all riprap installations experience some degree of failure within 10 years of construction. Refer to Section 6.5.3.2 for gravel bedding or filter design.

6.5.5.3 Design Considerations: The geometric properties of wire enclosed rock permit placement in areas where ordinary riprap is either difficult or impractical to place. Proper design and construction is important to successful operation and lifetime performance.

Slope Mattress Lining: Figure 6.11 shows a typical configuration for a gabion slope mattress channel lining. Mattresses and flat gabions on channel side slopes need to be tied to the banks by 1-inch diameter steel pipes driven 4 feet into tight, solid soil (clay) and 6 feet into loose soil (sand). The pipes should be located at the inside corners of basket diaphragms along an upslope (highest) basket wall, so that the stakes are an integral part of the basket. The exact spacing of the stakes depends upon the configuration of the baskets, however the following is the suggested minimum spacing: stake every six feet along and down the slope, for 2:1 slopes and every 9 feet along and down the slope for slopes flatter than 2:1. Channel linings should be tied to the channel banks with gabion counterforts (thickened gabion sections that extend into the channel bank) at least every 12 feet. Counterforts should be keyed at least 12 inches into the existing banks with slope mattress linings to counteract longitudinal movement.

Figure 6.11
Slope Mattress Lining
 (Wright-McLaughlin Engineers, 1969)

6.5.6 Toe Protection

6.5.6.1 General: Scour at a poorly designed toe of a channel bank is one of the major causes of failure of riprap or gabion protection measures. These failures result when the foundation of the bank protection measure is undermined by scour at the toe resulting from local scour and/or general channel bed degradation. Proper design of protection from toe scour involves two parameters. First, an estimate must be made of the maximum scour expected to occur over the design life of the structure. Second, a means of protection must be provided for the maximum scour. The first parameter, scour depth estimation, requires specialized analysis techniques by a qualified engineer. References for scour and sediment transport analysis are included in Section 6.7. Means of providing protection for the maximum scour—once it has been determined—are presented in this section.

6.5.6.2 Design Guidelines: The two methods of providing toe protection in alluvial channels are:

1. To extend protection to the maximum estimated depth of scour; and
2. To provide protection that adjusts to the scour as it occurs.

The first method is the preferred technique because the protection is initially placed to a known depth and the designer does not have to depend on uncertainties associated with the method that adjusts to the scour. The first method requires extension of the bank protection into the excavated channel bed and is primarily used for placement in the dry because of the expense and uncertainties of deep excavation that can frequently encounter groundwater.

The main advantage of the second method is the elimination of relatively deep excavation and related water control. The most frequently used material for providing adjustable toe protection is riprap placed at the toe of the bank in a weighted riprap configuration. The riprap moves downslope, as scour occurs, to form a protective cover. Figure 6.12a shows the desirable configuration for a weighted riprap toe. Less frequently used materials are gabion mattresses (see Figure 6.12b). These mattresses are anchored to the bank protection and their riverward ends are allowed to lower as scour occurs. Studies by Linder (1976) and the U.S. Army Corps of Engineers (December, 1981) on riprap toe protection arrived at the following conclusions:

1. Volume of rock in the weighted riprap toe is probably the most significant factor in determining the success of the weighted riprap toe.
2. Toe shape has a definite influence on performance. Thin toes do not release rock fast enough, which results in poor slope coverage. Thick toes release rock at a greater rate than is needed. The thickness of the recommended toe ranges from two to three times the thickness of the riprap bank protection. The recommended toe shape is shown in Figure 6.12a.
3. Complex toe designs that are difficult to construct are not necessary.
4. Downslope rock movement occurred without significant movement in the downstream direction.
5. Results from modeling and the subsequent prototypes show that the recommended weighted toe designs launch at a slope slightly steeper than 2:1.
6. Toe volume in the physical model was approximately equal to the volume needed to extend the bank protection to the maximum scour depth at a 2:1 slope. Linder (1976) recommends a toe volume equal to 1.5 times the volume of extending the bank protection to the maximum scour depth.

Weighted riprap toes have been used successfully for many years. However, success has not been universal. A common factor among the failures appears to be the presence of impinged flow on the bank. Therefore, the guidelines, herein, apply chiefly to flow conditions parallel to the bank. Where impinged flow is likely, then analyses must be made to determine an appropriate additional level of protection for such flow conditions.

6.5.7 Grass Lined Channels

Appropriate grass cover for Maricopa County includes: alfalfa for dry land and Bermuda grass for irrigated applications. Establishment or temporary irrigation will be required in most situations (see Table 6.2).

The designer should coordinate work with the appropriate jurisdictional agency to provide the most acceptable grass cover and irrigation method.

6.5.8 Other Forms of Channel Stabilization

Other, less common forms of channel stabilization may also be acceptable, provided that it can be demonstrated that the particular stabilization method proposed is capable of withstanding the hydraulic conditions which can occur within the channel.

6.6 Design Procedures

This section provides the user of this manual with checklists (procedures) to be followed during design, and with examples of design computations that can be followed in order to clarify the procedures that are used.

6.6.1 Artificial Channels

Table 6.8 is the checklist to be employed in the design of artificial channels. Most applications in Maricopa County will be able to follow the Simplified Design Procedure. Should conditions fall outside of the *Simplified Design Procedure*, the more rigorous procedure, as shown in the remaining steps, must be completed. In some instances, the conditions may be so complex that the design procedure for natural channels (see Section 6.6.2) will be required. Determination of water surface profiles is not always required; however, such a determination is necessary in all instances of spatially varied flow (i.e. side channel spillways) and where obstructions cross the channel (i.e. culverts, bridges, grade control structures, etc).

6.6.1.1 Conditions for Using the Simplified Design Procedure: The steps required for the *Simplified Design Procedure* are marked with an asterisk in Table 6.8 and can be used to design open channels that service minor drains and for major drains that meet the following conditions:

- Grade control established, and
- Design parameters within those listed in Table 6.3.

6.6.1.2 Conditions Beyond the Scope of the Simplified Design Procedure: When the conditions of the previous subsection cannot be met, it will be necessary to undertake a more detailed analysis that includes all of the steps listed in Tables 6.8 and 6.9. Table 6.8 addresses analytic requirements of natural channels and modifications that may be necessary to accommodate crossings of the waterways, such as bridges and culverts.

6.6.2 Natural Channels

Detailed analyses of natural channels and non-rigid artificial channels are beyond the scope of this manual; however, some understanding of the aspects of the analysis for non-rigid channels is necessary to proceed with the design of rigid channels and to provide initial analyses during the master planning phases, especially for lands adjacent to natural channels. Tables 6.8 and 6.9 are included to provide prospective designers with a comprehensive list of subjects that must be considered on adjacent developments and to plan effective countermeasures to potential adverse impacts.

In addition to normal resources a designer may have for analyzing non-rigid channels, four specific resources that were used to develop Table 6.10 are listed at the bottom of that table. Examination of these documents reveals the potential complexity of analysis of natural channels in Maricopa County. Few naturally occurring channels will have sufficient grade controls to be in equilibrium over the expected range of flows. This condition can have significant impacts on the design of related structures, such as culverts, hydraulic drops, and bridges. In addition, the designer should be alert to practices that are common within channels, such as gravel mining, that can have significant impact on structures and on the overall stability of the channel. It is very common for natural channels to move laterally during larger storm events, and this potential condition can result in serious consequences to adjacent land uses.

6.6.3 Design Example

Problem Description:

Improve a small earth lined channel with incised low flow, bank and edge erosion $S_o = 0.006$ ft/ft, partially vegetated sandy silt material to convey 100-year design flow, $Q_{100} = 565$ cfs.

Requirements:

- Use available channel width of 50 feet, with approximately 3 feet of depth.
- Provide grass-lined main channel with concrete-lined low flow.
- Use 4:1 side slopes and provide minimum freeboard allowance.

Solution:

A. Use Manning's Equation (Equation 6.1) to determine channel capacity.

1. Find cross-sectional area of flow, [Total area (A_T) = area of low flow channel (A_{lf}) + area of main channel (A_{mc})].

$$\begin{aligned}
 A_T &= A_{lf} + A_{mc} \\
 &= (1.5)(5) + 3((18 + 42)/2) \\
 &= 7.5 + 90 \\
 A_T &= 97.5 \text{ sf}
 \end{aligned}$$

2. Find wetted perimeter and indicate a 4" thickness for low flow wall.

$$\begin{aligned}
 P_T &= P_{lf} + P_{mc} \\
 &= [2(0.33) + 2(1.5) + 5] + [(18 - 5.67) + 2(3)(1^2 + 4^2)^{0.5}] \\
 &= 8.67 + (12.33 + 24.7) \\
 P_T &= 45.7 \text{ ft}
 \end{aligned}$$

3. Find hydraulic radius.

$$\begin{aligned}
 R &= A_T / P_T \\
 &= 97.5 / 45.7 \\
 R &= 2.13 \text{ ft}
 \end{aligned}$$

4. Determine Manning's "n" from Table 6.11.

Find composite "n" value:

Concrete lined low flow: $n = 0.015$

Grass-lined main channel: $n = 0.025$

$$n = \left[\frac{\sum_i (P_i n_i^{1.5})}{P_T} \right]^{0.67}$$

$$n = \left[\frac{(P_{lf})(n_{lf}^{1.5}) + (P_{mc})(n_{mc}^{1.5})}{P_T} \right]^{0.67}$$

$$n = \left[\frac{8.67(0.015)^{1.5} + 37.0(0.025)^{1.5}}{45.7} \right]^{0.67}$$

$$n = \left[\frac{0.016 + 0.15}{45.7} \right]^{0.67}$$

$$n = 0.023$$

5. Substitute values to solve for slope and multiply Equation 6.1 by A_T and rearrange:

$$Q = (1.49 / n) A_T R^{0.67} S_o^{0.5}$$

$$S_o = [Q n / (1.49 A_T R^{0.67})]^2$$

$$= [565(0.023) / (1.49)(97.5)(2.13)^{0.67}]^2$$

$$S_o = 0.0029 \text{ ft/ft}$$

Since a channel bottom slope of 0.0029 ft/ft is sufficient to convey the design flow of 565 cfs, the steeper existing S_o of 0.006 ft/ft will convey the flow with a smaller cross sectional area. Equation 6.1 can be solved for $A_T R^{0.67}$ to determine the actual cross section of flow:

$$\begin{aligned} A_T R^{0.67} &= Q n / 1.49 S_o^{0.5} \\ &= 565 (0.023) / 1.49 (0.006)^{0.5} \\ &= 112.6 \text{ ft}^{2.67} \end{aligned}$$

By trial and error,

$$\begin{aligned} Y_b &= 2.45 \text{ ft,} \\ A_T &= 7.5 + 2.65((18 + 37.6)/2) = 75.6 \text{ sf,} \\ P_T &= 8.67 + ((18 - 5.67) + 2(2.45)(1^2 + 4^2)^{0.5}) = 41.2 \text{ ft, and} \\ R &= A_T / P_T = 75.6 / 41.2 = 1.83 \text{ ft.} \end{aligned}$$

Flow along the channel at $S_o = 0.006$ ft/ft has reduced the water depth by 0.55 ft. Note that the composite "n" value has not changed with the new values of P_{bc} , P_{me} , and P_T .

B. Check velocity and Froude Number.

1. Check velocity.

$$V = Q / A$$

$$= 565 / 75.6$$

$$V = 7.5 \text{ fps} > 6 \text{ fps}$$

6 ft/s allowable for Bermuda grass lined channels with erosion resistant soil only.

2. Check the Froude number.

$$\begin{aligned} F_r &= V / (gD)^{0.5} \\ &= 7.5 / [(32.2)(75.6) / (37.6)]^{0.5} \end{aligned}$$

$$F_r = 0.93 > 0.86$$

The channel is under near critical flow conditions and will not be stable at a bottom channel slope of 0.006 ft/ft for the design flow. One solution is to provide grade control structures to maintain $S_o = 0.0029$ ft/ft, thereby having $V = QA = 565/97.5 = 5.8$ fps and $F_r = V/(gD)^{0.5} = 5.8/((32.2)(97.5/42))^{0.5} = 0.67$, which is within the acceptable range of subcritical flow. See Chapter 7 for grade control structures.

3. Check channel transitions (see Chapter 7).

C. Check freeboard requirement.

Using the revised slope of $S_o = 0.0029$ ft/ft, and velocity of $V = 5.8$ fps.

$$\begin{aligned} FB &= 0.25 (Y + V^2 / 2g) \\ &= 0.25 (3 + 5.8^2 / 2(32.2)) \\ &= 0.25 (3.52) \end{aligned}$$

$$FB = 0.88 \text{ ft}$$

Use 1 ft.

Summary:

Use grass lined channel with 4:1 side slopes.

Velocity = 5.8 fps; $F_r = 0.67$, subcritical flow. See Table 6.2 for allowable grass and soil types.

Channel slope = 0.0029 ft/ft << 0.006 ft/ft (existing).

Provide grade control.

Provide 1 foot minimum freeboard allowance.

Check flow velocities and hydraulic properties for other flows anticipated.

Hydraulic Structures

7.1 Definition of Symbols

The following symbols are used in equations throughout Chapter 7:

α	=	Angular variation of sidewall with respect to channel centerline
α_1	=	Kinetic energy correction coefficient
β	=	Standing wave front angle
ρ	=	Density of water, 1.94 lbs s ² /ft ⁴
τ	=	Shear stress on the bed caused by the flow of water, psi
γ	=	Specific weight, lb/ft ³
A	=	Area (subscripts as shown in the Figures), ft ²
b	=	Bottom width, ft
b_t	=	Trickle channel width, ft
B	=	Basin depth below downstream channel, ft
C_d	=	Drag force coefficient
C_p	=	Coefficient of mean pressure fluctuations from mean pressure levels in a hydraulic jump
C_{p-max}	=	Coefficient of maximum pressure fluctuations from mean pressures level in a hydraulic jump
C_w	=	Lane's Weighted-creep ratio
d_2	=	Depth of basin tailwater = $Y_2 + B$, ft
d_{50}	=	Grain diameter corresponding to 50% passing, by weight (or mass), ft, mm
d_s	=	Depth of scour, ft
D	=	Jet plunge height, ft
D_b	=	Bedding layer thickness, ft
D_g	=	Grout depth, ft
D_{jm}	=	Distance to the hydraulic jump, main channel, ft

D_{jt}	=	Distance to the hydraulic jump, trickle channel, ft
D_n	=	Drop number
D_r	=	Rock depth, ft
EGL_m	=	Energy grade line along the main portion of a drop
EGL_t	=	Energy grade line along trickle channel through a drop
El_c	=	Water surface elevation of criteria depth at the crest of a drop
El_m	=	Elevation of crest of a drop at main channel invert drop
El_t	=	Elevation of crest of a drop at trickle channel invert
F_b	=	Force at bend, lb
F_j	=	Impact force of flow jet, lb
F_m	=	Momentum force, lb
F_r	=	Froude number = $V/(gy_m)^{0.5}$
F_{r1}	=	Froude number upstream of the jump
F_s	=	Specific force, ft ²
g	=	Acceleration due to gravity, 32.2 ft/sec ²
h	=	Height of the wingwalls above the main crest, ft
h_j	=	Height of hydraulic jump, ft
h_L	=	Head loss, ft
h_s	=	Depth of scour, ft
h_v	=	Velocity head, ft
H	=	Head on the weir, ft
H_b	=	Height of a baffle
H_{cw}	=	Height of seepage cutoff, ft
H_d	=	Desired drop across structure, ft
H_{dr}	=	Differential head between analysis points, ft
H_m	=	Total energy head at the crest of the main drop, ft
H_s	=	Differential head, usually at a drop; the difference between the upstream water surface (normal depth) to the downstream tailwater, or the head difference between analysis points (e.g. to point of supercritical flow minimum depth), ft
H_t	=	Total energy at the crest of the trickle channel, ft
H_w	=	Head on structure for weighted-creep ratio, (headwater-tailwater), ft
L_a	=	Approach length, ft
L_{bm}	=	Design basin length, main channel, ft
L_{bt}	=	Design basin length, trickle channel, ft
L_d	=	The drop length, for vertical hard drop the distance from the crest wall to the point where the flow nappe contacts the basin floor, ft
L_{dm}	=	Nappe length, main channel, ft
L_{dt}	=	Nappe length, trickle channel, ft
L_H	=	Horizontal creep distance along contact surfaces less than 45 degrees, ft
L_j	=	Length of the hydraulic jump (approximately $6 Y_2$), ft

L_s	=	Length of scour, ft
L_v	=	Vertical creep distance along any contact surfaces greater than 45 degrees, ft
M	=	Mass rate of flow, lb s/ft = ρQ
n	=	Manning roughness coefficient
P	=	For a vertical drop structure, the height of the weir crest above the approach channel, ft
ΔP	=	Maximum pressure fluctuation at a given location within a hydraulic jump, psi
q	=	Discharge per unit width, cfs/ft
q_c	=	Discharge per unit width of crest, cfs/ft
q_m	=	Discharge per unit width of the main channel at drop, cfs/ft
q_t	=	Discharge per unit width of the trickle channel at drop, cfs/ft
Q	=	Maximum design discharge, cfs
r	=	Channel centerline radius of curvature, ft
R	=	Hydraulic radius, ft
S_o	=	Bed or drop slope (S is also used), ft/ft
T	=	Top width of flow in the channel, ft
TW	=	Tailwater depth, ft
v_c	=	Critical velocity, ft/s
V	=	Velocity, ft/s
W	=	Width, ft
W_s	=	Width of scour, ft
y	=	Depth of flow, ft
y_c	=	Critical flow depth, ft
y_{cm}	=	Critical depth at a drop in the main channel, ft
y_{ct}	=	Critical depth at a drop in the trickle channel, ft
y_e	=	Equivalent depth, ft
y_f	=	Vertical fall at a drop, ft
y_m	=	Hydraulic depth (area / top width), ft
y_n	=	Normal depth, ft
y_p	=	At a vertical drop, the pool depth under the nappe just below the crest, ft
Y_1	=	Initial (upstream) flow depth, ft
Y_2	=	The tailwater depth required to cause a jump to form immediately downstream of the initial depth location for Y_1 , ft
$(Y_2)_m$	=	Sequent depth, main channel, ft
$(Y_2)_t$	=	Sequent depth, trickle channel, ft
Y_f	=	Effective fall height from the crest to the basin floor, ft
Y_o	=	Brink depth, ft
Y_p	=	Pool depth under the nappe downstream of the crest, ft

Y_{tw}	=	Actual tailwater depth present downstream of the drop, ft
z	=	For a vertical drop structure, the difference in the bed elevations of the approach channel at the weir and the downstream channel at the end of the structure, ft
Z	=	Channel side slope horizontal distance per foot of drop, ft/ft
Z_f	=	Drop face slope, ft/ft

7.2 Use of Structures in Drainage

Hydraulic structures are used in storm drainage works to control water flow characteristics such as velocity, direction and depth. Structures may also be used to control the elevation and slope of a channel bed, as well as the general configuration, stability and maintainability of the waterway.

The use of hydraulic structures can increase the cost of drainage facilities. The use of hydraulic structures should be limited by careful and thorough hydraulic engineering practices to locations and functions justified by prudent planning and design. On the other hand, use of hydraulic structures can reduce initial and future maintenance costs by changing the characteristics of the flow to fit the project needs, and by reducing the size and cost of related facilities.

Hydraulic structures include channel drop structures, low flow check structures, energy dissipators, bridges, transitions, chutes, bends and many other specific drainage works. Depending on the function to be served, the shape, size and other features of hydraulic structures can vary widely from project to project. Hydraulic design procedures (including model testing in some cases) that examine the structure and related drainage facilities are a key part of the final design for all structures.

This chapter is oriented toward control structures for drainage channels, outlets for storm drains and culverts—in contrast to dams, spillways or specialized conveyance measures.

7.2.1 Channel Drop Structures

Drop structures are used to reduce the effective slope of a natural or artificial channel. Typically, a drop structure extends across the entire width of the channel and provides grade control for a full range of flows.

Check structures are similar in concept, but their objective is to stabilize and control the channel bed or low flow zone. During a major flood, portions of the flow circumvent the structure, but erosion is maintained at an acceptable level. Overall stability is maintained

by control of the low flow area, which would otherwise degrade downward. A series of check structures can be an economical interim grade control measure for natural channels in urbanizing areas or for artificial channels where funding is inadequate for construction of drop structures.

7.2.2 Conduit Outlet Structures

Energy dissipation structures are necessary at the outlets of culverts or storm drains to reduce flow velocity and to provide a transition whereby the concentrated, high velocity flow exiting the conduit is changed to a wider, shallower and non-erosive flow. Outlet structures may be preformed rock riprap stilling basins or reinforced concrete structures such as impact basins.

7.2.3 Special Channel Structures

Bridges, spur dikes, channel transitions, constrictions and bends, and structures for lined channels and for long conduits are examples of hydraulic structures used for special applications.

7.2.3.1 Bridges and Related Structures: Bridges have the potential advantage of crossing a waterway without disturbing the flow. However, for overall economic and structural reasons, encroachments and piers in the waterway are a practical reality. A bridge structure can cause significant hydraulic effects, such as an increase in the water surface elevation, and channel scour. These conditions must be analyzed and measures must be designed for mitigation of negative impacts. Spur dikes, levees, drop or check structures, and pier and abutment protection are types of structures designed to control hydraulic effects at bridge crossings. Refer to Chapter 5 for further discussion on bridges.

7.2.3.2 Channel Transitions: Channel transitions are typically used to moderately vary the cross-sectional geometry to allow the waterway to fit within a more confined right-of-way, or to purposely accelerate the flow to be carried by a specialized high velocity conveyance structure. Constrictions are designed to restrict and reduce the conveyance along a short reach. Examples are a bridge with roadway approach embankments that significantly encroach into a floodplain, or a structure designed to raise the upstream water surface to force spills into an off-channel storage facility. An expansion structure is usually required at the downstream end of a constricted channel reach or structure to provide a safe, non-eroding transition to the unconstricted channel. Potential conditions for creation of a hydraulic jump must be examined and provisions made for control of a jump and associated turbulent flow conditions.

7.2.3.3 Structures for Lined Channels and Long Conduits: Acceleration chutes can be used to maximize the use of limited downstream right-of-way, and to reduce downstream channel and pipe costs. However, chutes should only be used where good

hydraulic and environmental design concepts permit the use of high velocity flow. In general, high velocity flow is not permitted in urban areas and applications in other areas will require careful scrutiny. Bends in lined channels and closed conduits require analysis to determine if supercritical flow occurs, or if special structural and other design considerations are needed.

7.2.4 Factors of Safety

Specific calculations to determine foundation stability and factors of safety against sliding, uplift, and overturning for a hydraulic structure are necessary in the design of safe structures. The factor of safety derived for a particular case depends, to a large degree, on the risk and consequence of failure. Therefore, the selected factor of safety must be appropriate for each structure being designed.

The factors of safety for sliding, uplift, and overturning all may be different for a particular structure. A general range of 1.5 to 2.0 for these factors is recommended for many types of structures subjected to a variety of loading conditions (see: *Preliminary Engineering Manual, Civil Works Construction* [USACE, January 1948]; *Design Manual, Foundations and Earth Structures* [U.S. Navy, May 1982]; *Design of Small Dams* [USBR, 1987]; *Design of Gravity Dams* [USBR, 1976]; and *Drainage of Roadside Channels with Flexible Linings* [USDOT, FHWA, March 1986].

7.3 Channel Drop Structures

7.3.1 General

The term drop structure is broadly defined. Included are structures built to restore previously damaged channels, those constructed during new urban development to prevent accelerated erosion caused by increased runoff, and applications in which other specialized hydraulic conditions are created in the flow channel.

The focus of this design guideline is on drop structures with design flows up to 10,000 cfs. Flows less than 500 cfs are in the usual range for check structures. Check structures have additional considerations because major flooding goes around the structure abutments, typically in a much wider floodplain.

7.3.1.1 Basic Components of a Drop Structure: Figure 7.1 shows a typical channel drop structure with its various components. Once a particular structure type is selected for design, analyses are conducted to determine the optimal sizing or extent of the various components.

 (Adapted from McLaughlin Water Engineers, Ltd. 1986)

7.3.1.2 Design Considerations: In addition to hydraulic performance (discussed in Section 7.3.2), a number of other considerations affect the selection of an appropriate drop structure for a particular application.

Soil and Foundation Conditions: Geotechnical investigations should be completed to identify the characteristics of the on-site soils. Silty and sandy soils require detailed analyses for seepage control. Expansive soils require special design techniques to minimize differential movement. Structure design for foundation, walls and slabs must consider soil and hydrostatic pressures, seepage and potential scour.

Construction Concerns: The selection of a drop and its foundation may also be tempered by construction difficulty, access, material availability, etc. Quality control through conscientious inspection is an important consideration.

Maintenance Concerns: Issues to be considered in the design include, ease of access to the crest and stilling basin areas, vandal resistance, eliminate trapped (ponded) water, sediment accumulation, and landscaped or grassed slopes that are easily maintained.

Sociological Considerations: These include public acceptability issues such as safety (Section 7.6), visual appearance (Section 7.7), mosquito breeding in ponded water, etc.

7.3.1.3 Drop Structure Types: Design guidance is presented in this section for the following drop structures:

- Baffle Chute Drops
- Vertical Hard Basin Drops
- Vertical Riprap Basin Drops
- Sloping Concrete Drops
- Low Flow Check Structures

Figure 7.2 shows schematic profiles of each type.

Due to a high failure rate and excessive maintenance costs, drop structures having loose riprap on a sloping face are not permitted.

All drop structures should be inspected on a regular basis during construction to assure their quality and integrity. In addition, drop structures must be monitored on a periodic basis after construction.

Additional bank and bottom protection may be needed if secondary erosional tendencies are revealed. Thus, it is advisable to establish construction contracts and budgets with this in mind. Use of standardized design methods for the types of drops described herein can reduce the need for secondary design refinements. Section 7.3.3 presents considerations for the selection of the appropriate type of drop structure for particular application or site conditions.

7.3.2 Hydraulic Analysis Considerations

7.3.2.1 General Procedures: These design procedures are generalized. Use them to identify the most suitable approach, with the understanding that detailed analytical methods and design specifications may vary as a function of site conditions and hydraulic performance. A standard drop structure design approach would include at least the following steps:

1. Define the maximum design discharge (usually the 100-year) and other discharges appropriate for analysis (selected discharge(s) expected to occur on a more frequent basis, which may behave differently at the drop).
2. Select possible drop structure alternatives to be considered (Section 7.3.3).
3. Determine the required longitudinal channel slope and the total drop height required to produce the desired hydraulic conditions.
4. Establish the channel hydraulic parameters, reviewing drop structure and channel combinations that may be most effective.
5. Conduct hydraulic analyses for the structure. Where appropriate, apply separate hydraulic analyses to the main channel and the low flow zones of the drop to determine the extent of protection required, as well as the potential problems/solutions for each. (See Section 7.3.2.3 for discussion.)
6. Perform soils and seepage analyses to obtain foundation and structural design information. Combine seepage and hydraulic analysis data to determine forces on the structure. Evaluate uplifting, overturning, and sliding.
7. Evaluate alternative structures in terms of their estimated capital and maintenance costs, and identify comparable risks and problems for each alternative. Review alternatives with client and jurisdictional agency to select final plan. (This task is not specifically a part of the hydraulic analysis criteria, but is mentioned to illustrate other factors which are involved in the analysis of alternatives.)
8. Use specific design criteria to determine the drop structure dimensions, material requirements and construction methods necessary to complete the design for the selected structures.

7.3.2.2 Crest and Upstream Hydraulics: Usually, the starting point of drop analysis and design is the designation of the crest section (or review of existing configuration) at the top of the drop. As flow passes through critical depth near the crest, upstream hydraulics are separated from downstream. The critical flow state must be calculated and compared with the downstream tailwater effect which may submerge the crest and effectively control the hydraulics at the crest.

With control at the drop crest, upstream water surface profile computations are used to estimate the distance that protection should be maintained upstream, that is, the distance to where localized velocities are reduced to acceptable values. Backwater computations also yield the maximum upstream flow depth used to set wall abutment and bank heights. The water surface profile computations should include a transition/contraction head loss, which should typically range from 0.3 (modest transitions) to 0.5 (more abrupt transitions) times the change in velocity head. The reader should refer to standard hydraulic references for guidance (i.e., Chow 1959). For a given discharge, there is a balance between the crest base width, upstream and downstream flow velocities, the Froude Number in the drop basin, and the location of the jump. These parameters must be selected for each specific application.

Two basic configurations of crests are assumed. Baffle chutes, vertical hard basin and vertical riprap basin drops frequently have vertical or nearly vertical abutments with nearly rectangular cross sections. Sloping concrete drops generally have sloping abutments, forming a trapezoidal crest cross section. All drop types would typically have a low flow channel which is extended through the drop crest section at the channel invert.

Vertical or Near Vertical Abutments at Drop Crest: Figure 7.3 presents alternative drop crests at a vertical drop structure. In general, the objectives of upstream hydraulics and crest design are:

1. To maintain freeboard in the approach channel,
2. To optimize crest and basin dimensions to achieve the most cost-effective structure, and
3. To prevent erosion in the transition zone, where flow accelerates approaching the crest.

A crest expansion may be necessary to maintain adequate freeboard in the upstream channel and reduce drawdown velocities just upstream of the crest. A crest constriction may be appropriate for wide channels to reduce the cost of the crest wall.

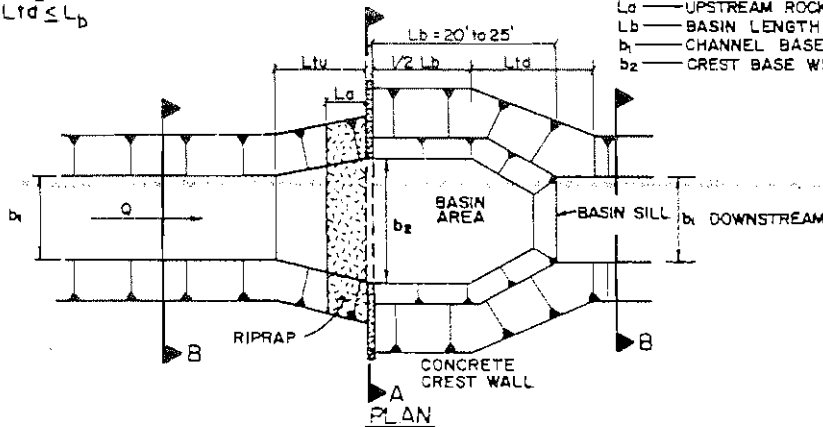

Sloping Abutments at Drop Crest: Figure 7.4 shows a schematic layout for the drop crest and upstream channel at a sloping drop structure. The design objectives discussed previously also apply here. Constricting the trapezoidal crest serves to economize the structure while maintaining upstream freeboard. The seepage cutoff wall is typically placed at or near the upstream end of the transition zone and the zone protected with concrete or grouted rock. This arrangement also provides better seepage control, as discussed in Section 7.3.2.5.

7.3.2.3 Water Surface Profile Analysis: Backwater computations should be completed for the channel reaches upstream and downstream of the proposed drop structure to establish approach flow conditions and tailwater conditions for the range of design flows.

The next step is to determine the location of the hydraulic jump so that the stilling basin can be sized to adequately contain the zone of turbulence. The determination of the hydraulic jump's location is usually accomplished through the comparison of the unit specific force for the supercritical inflow and the downstream subcritical flow. For vertical drop structures, this requires analysis of the tailwater elevation to determine if it is sufficient to cause the jump to occur immediately, or if the jet will wash downstream until the specific force is sufficiently reduced to allow the jump to occur.

For sloping drop structures, water surfaces must be determined for the supercritical profiles down the face of the drop. The location of the hydraulic jump can be determined by using Equation 7.1 to compute the unit specific force F_s , above and below the toe of the drop. The hydraulic jump, in either the trickle channel or the main drop, will begin to form where the unit specific force of the downstream tailwater is greater than the specific force of the supercritical flow below the drop.

$$F_s = \frac{q^2}{gy} + \frac{y^2}{2} \quad (7.1)$$

The depth y , for downstream specific force determination, is the tailwater surface elevation minus the ground elevation at the point of interest, which is typically the main basin elevation or the trickle channel invert (if the jump is to occur in the basin). The depth for the upstream specific force (supercritical flow) is the supercritical flow depth at the point in question.

For jumps in vertical riprap basins, the user has to rely on the criteria derived from laboratory studies. The shaping or reshaping of riprap influences the jump stability and location. Nevertheless, the basic specific force equation provides some guidance.

Ideally, for economic considerations, the jump should begin no further downstream than the drop toe. This is generally accomplished in the main drop zone by depressing the basin to a depth nearly as low as the downstream trickle channel elevation.

Analysis should be conducted for a range of flows, since flow characteristics at the drop can vary with discharge. For example, the 10-year flow may cascade down the face of a sloping drop and form a jump downstream of the toe, whereas the 100-year flow may totally submerge the drop.

Where a major channel incorporates a low flow channel, separate analyses should be completed for the low flow zone and the major channel overbank zone. This is because the deeper flow profile in the low flow channel zone has a higher energy grade line profile (Figure 7.5). Specific force analysis in this zone shows that the hydraulic jump will not occur in the same location as the rest of the flow over the drop, and in most cases the jump will occur further downstream. Separate analysis for this condition will assure that the stilling basin length is sufficient to contain the jump.

HYDRAULIC ANALYSIS SECTION AT CREST OF DROP

HYDRAULIC ANALYSIS PROFILE FOR SLOPING DROP

Figure 7.5
Typical Section and Profile for Sloping Drop
(McLaughlin Water Engineers, Ltd. 1986)

7.3.2.4 Hydraulic Jump: With the exception of the baffle chute drop, all of the drop structures described herein use the formation of a hydraulic jump to dissipate energy. A discussion of this hydraulic phenomenon is presented as follows.

A hydraulic jump occurs when flow changes rapidly from low stage supercritical flow to high stage subcritical flow. Hydraulic jumps can occur: 1) when the slope of a channel abruptly changes from steep to mild; 2) at sudden expansions or contractions in the channel section; 3) at locations where a barrier, such as a culvert or bridge, occurs in a channel of steep slope; 4) at the downstream side of dip crossings or culverts; and 5) where a channel of steep slope discharges into other channels.

Hydraulic jumps are useful in dissipating energy, and consequently they are often used at drainageway outlet structures and drop structures as an efficient way to minimize the erosive potential of floodwaters. However, because of the high turbulence associated with hydraulic jumps, they must be contained within a well-protected area. Complete computations must be made to determine the height, length and other characteristics of the jump (including consideration of a range of flows) in order to adequately size the containment area.

The type of hydraulic jump that forms, and the amount of energy that it dissipates, is dependent upon the upstream Froude number (F_1). The various types of hydraulic jumps that can occur are listed in Table 7.1.

Jump Height: The depth of flow immediately downstream of a hydraulic jump is referred to as the sequent depth (Y_2). The sequent depth in rectangular channels whose upstream Froude number is ≥ 1.7 , can be computed by use of the following equation:

$$Y_2 = \frac{1}{2} Y_1 [(1 + 8F_1^2)^{1/2} - 1] \quad (7.2)$$

The solution for sequent depth in trapezoidal channels can be obtained from a trial-and-error solution of Equation 7.3, which is derived from momentum equations. It is also acceptable for design purposes to determine the sequent depth in trapezoidal channels from Equation 7.2. Equation 7.2 is much simpler to solve and produces only slightly greater values for sequent depth than does Equation 7.3.

$$\frac{ZY_1^3}{3} + \frac{ZY_1^2}{2} + \frac{Q}{gA_1} = \frac{ZY_2^3}{3} + \frac{bY_2^2}{3} + \frac{Q}{gA_2} \quad (7.3)$$

Table 7.1
Types of Hydraulic Jumps

Upstream Froude Number	Type of Jump	Energy Loss, %
$1.0 < F_1 \leq 1.7$	Undular Jump	0.5
$1.7 < F_1 \leq 2.5$	Weak Jump	5 to 18
$2.5 < F_1 \leq 4.5$	Oscillating Jump	18 to 44
$4.5 < F_1 \leq 9.0$	Steady Jump	44 to 70
$9.0 < F_1$	Strong Jump	70 to 85

Figures 7.6 and 7.8 provide graphs of hydraulic jumps for a horizontal rectangular channel and a horizontal trapezoidal channel, respectively.

Undular Jump: An undular hydraulic jump is the type of jump which occurs where the upstream Froude number is between 1.0 and 1.7. This type of jump is characterized by a series of undular waves which form on the downstream side of the jump. Experiments have shown that the first wave of an undular jump is higher than the height given by Equation 7.3. Therefore, the height of this wave should be determined as follows:

$$\frac{Y_2 - Y_1}{Y_1} = F_{r1}^2 - 1 \quad (7.4)$$

Jump Length: The length of a hydraulic jump is defined as the distance from the front face of the jump to a point immediately downstream of the roller. Jump length can be determined from Figures 7.7 and 7.9.

Surface Profile: The surface profile of a hydraulic jump may be needed to design the extra bank protection, or training walls for containment of the jump. The surface profile can be determined from Figure 7.10.

Jump Location: In most cases a hydraulic jump will occur at the location in a channel where the initial and sequent depths and initial Froude number satisfy Equation 7.3. This location can be found by performing direct-step calculations in either direction toward the suspected jump location until the terms of the equation are satisfied. Specific force analysis can then be used by employing Equation 7.1 to establish where a jump will occur. The hydraulic jump will begin to form where the unit specific force of the downstream tailwater is greater than the unit force of the supercritical approach flow.

Design Charts and Figures: Figures 7.6 to 7.10 and table 7.2 have been included as additional aids to the user of this manual.

7.3.2.5 Seepage and Uplift Forces: The most common technique for seepage analysis is that proposed by E.W. Lane (1935), commonly referred to as "Lane's Weighted-Creep Method. The essential elements of this method are paraphrased as follows:

1. The weighted-creep distance of a cross-section of a drop structure is the sum of the vertical creep distances (along contact surfaces steeper than 45 degrees), L_v , plus one-third of the horizontal creep distances (along contact surfaces less than 45 degrees), L_H .
2. The weighted-creep head ratio is defined as:

$$C_w = \frac{(L_H + 3L_v)}{3H_{df}} \quad (7.5)$$

3. Lane's recommended weighted-creep ratios are given for various foundation materials in Table 7.3.
4. Reverse filter drains, weep holes, and pipe drains are aids to provide security from seepage, and recommended safe weighted-creep head ratios may be reduced as much as 10 percent, if used.
5. Care must be exercised to insure that cutoff walls extend laterally into each bank so that flow will not outflank them.
6. The upward pressure to be used in design may be estimated by assuming that the drop in pressure from headwater to tailwater along the contact line of the drop structure and cutoff wall is proportional to the weighted-creep distance.

Seepage is controlled by increasing the seepage length such that C_w is lowered to a conservative value. Soils tests must be taken during design and confirmed during construction. These tests are especially critical for reinforced concrete structures.

An example of this technique can be found in Design of Small Dams (USBR, 1987). An alternative approach is to use a flow net or computerized seepage analysis to estimate subsurface flows and uplift pressures under a structure. Seepage considerations should be included in the design of cutoff walls, wall footings, drains, filters, structural slabs, and grouted masses.

Locating a seepage cutoff wall upstream of the crest of a drop structure and using horizontal impervious blankets can be effective. It is also very important to control lateral seepage around the structure.

Table 7.3
Lane's Weighted-Creep: Recommended Ratios

Material	C_w Ratio
Very fine sand or silt	8.5
Fine sand	7.0
Medium sand	6.0
Coarse sand	5.0
Fine gravel	4.0
Medium gravel	3.5
Coarse gravel including cobbles	3.0
Boulders with some cobbles and gravel	2.5
Soft clay	3.0
Medium clay	2.0
Hard clay	1.8
Very hard clay or hardpan	1.6

7.3.3 Drop Selection

There are four major considerations for the selection of the type of drop structure for a particular application: 1) surface flow hydraulic performance; 2) foundation and seepage control; 3) economic considerations; and 4) construction considerations. Other factors which can affect selection are land uses, aesthetics, safety, maintenance, and anticipated downstream channel degradation.

7.3.3.1 Surface Flow Hydraulic System: The primary consideration for the selection of a drop structure should be functional hydraulic performance. The surface flow hydraulic system combines channel approach and crest hydraulics, sloping or vertical drop hydraulics and downstream tailwater conditions. Hydraulic analysis procedures are presented in Section 7.3.2. Additional guidelines are also contained in Section 7.3.4.

7.3.3.2 Foundation and Seepage Control Systems: Table 7.4 presents some typical foundation conditions and control systems typically used for various drop heights. Table 7.4 is presented only as a guide. The hydraulic engineer must calculate hydraulic loadings which can occur for a variety of conditions such as interim construction conditions, low flow, and flood flow. The soils/foundation engineer couples this information with the on-site soils information. Both work with a structural engineer to establish final loading diagrams, and selection and sizing of structural components. This

Table 7.4

** (excavate onto bedrock and set into concrete)

Legend

S Sheet pile
 SwB Sheet pile with bracing and extra measures
 CTc Cutoff Trench backfilled with concrete
 ST Slurry Trench; similar to CTc; but trench walls are supported with slurry and then later replaced with concrete or additives that effect cutoff
 CW Cutoff Wall; conventional wall, possibly with footer, backfilled; note that the effective seepage length should generally be decreased because of backfill
 CTI Cutoff Trench with synthetic liner and fill
 CTf Cutoff Trench with clay fill

section presents information relevant to hydraulics, but refer to geotechnical and structural books for related information.

7.3.3.3 Economic Considerations: Evaluation of alternative drop structure costs should include consideration of construction costs and maintenance costs. Construction costs include site work specific to the structure, seepage control, excavation, reinforced concrete, riprap, boulders, grout and backfill. Maintenance costs include rock replacement, debris removal, erosion repair, structural repairs, graffiti and silt removal. A standard method of cost comparison is present-worth analysis by which estimated maintenance costs are converted to present worth amounts by applying an appropriate discount rate factor. The present worth maintenance cost is then added to the construction cost of each structure under consideration for comparison.

Other factors also affect the economics of alternative types of drop structures. In many cases, specific site requirements may dictate the direction of drop structure design. Depending on location, some construction materials, such as riprap or boulders, may not be readily available at reasonable cost. Analysis may include consideration of the cost of a single drop structure 3 feet high versus the cost of two structures, each 1.5 feet high.

7.3.3.4 Construction Considerations: The selection of a drop and its foundation may also be tempered by construction difficulty, location, access, and material availability/delivery. Table 7.5 lists construction considerations for key drop structure materials. Additional discussion of construction concerns is included with the design guidelines for each drop type in the following section.

7.3.4 Design Guidelines for Drop Structures

7.3.4.1 Baffle Chute Drops: The USBR has developed design standards for a reinforced concrete chute with baffle blocks on the sloping face of the drop, which is commonly referred to as baffled apron or baffle chute drops. There are excellent references, *Hydraulic Design of Stilling Basins and Energy Dissipators* (Peterka, 1984), and *Design of Small Canal Structures* (USBR, 1974), that should be used for the design of these structures. Another reference is *Baffled Apron as Spillway Energy Dissipator* (Rhone, 1977), which evaluates higher design discharges, and entrance modifications to reduce the backwater effect caused by the baffles.

The optimal performance occurs for a unit flow (q) at the chute width of 35 to 60 cfs/ft. Model testing has evaluated discharges up to 300 cfs/ft, and there have been structures built with up to 120 cfs/ft. The USBR states that the recommended design flow of 60 cfs/ft for baffle chute drops has been exceeded at several locations without causing significant problems.

Table 7.5
Construction Components Concerns and Quality Control Measures of Drop Structures

Type	Quality Concerns	Quality Control Measures and Inspection
Concrete	The major concern is strength and ability to resist weathering. Aggregate strength and durability are important. Special architectural treatments include exposed aggregate, form liners, and color additives.	Preconstruction items include review of shop drawings for reinforcing steel, formwork patterns and ties, concrete design mix and related tests, color additives or coatings and architectural treatments such as form liners, handrails and fences. Any architectural test samples should be completed and approved, along with all coatings, weather protection or other items which could affect appearance.
Reinforcing Steel	Usually not a problem unless the wrong grade of steel is brought to job, or site conditions are conducive to corrosion problems. Epoxy coated reinforcement can be specified for critical conditions.	During construction there are numerous items which require checking, including: rebar placement, formwork, tie placement, weep holes and drains, form release coatings and form cleaning before concrete placement, form removal, concrete placement and testing, weather protection, sealants, tie hole treatment, concrete finish work, and earthwork, especially that related to seepage control.
Riprap and Rock	<p>Hardness is of concern because the rock is subject to rough handling and impact forces.</p> <p>Durability concerns are: Oxidation, weathering (freeze thaw tests), and leaching or dissolving by water.</p> <p>Fraenuring, which leads to odd or undesirable shapes, is to be avoided.</p> <p>Seams or other discontinuities can lead to breakup or undesirable shapes and damage during handling.</p> <p>Geologic type is important; sedimentary rocks are undesirable. Volcanic rock often has low density.</p> <p>Density of the rock requires specific gravity tests.</p>	<p>A significant effort is needed in the area of rock quality control. Submittals should be required from suppliers to document quality. Rock should be durable, sound, and free of seams or fractures. The specific gravity should be a minimum of 2.40.</p> <p>Specifications should include requirements for orderly procedures and appropriate equipment, both for rock and grout placement. Gradation, durability and specific gravity tests of riprap at the quarry are needed, and should only be waived for small projects where the quarry can demonstrate recent tests. Handling that results in excessive breakage should result in changed methods and/or reexamination of rock quality. Subgrades should be dewatered and stabilized. Filters and bedding layers should be reviewed for compatibility to the on-site soil conditions. Rock handling and placement is critical. Riprap should be handled selectively so that the gradation is reestablished through any given vertical section. Areas where the thickness is comprised of all materials smaller than the d_{50}, or where excessive voids or radical surface variations occur should be reworked.</p> <p>Good placement techniques should result in a riprap layer with surface materials d_{50} size or greater, closely spaced with voids thoroughly chinked and locked between larger rock, top surfaces generally parallel to the plane of the overall riprap bank or surface, and no great departures in surface elevation from rock to rock.</p> <p>Graded riprap should not be used for grouting, as the smaller rock can prevent full penetration of the grout to the subgrade and can cause incomplete filling of the voids. Large rock or boulders should be placed with a gradall or multi-prong grapple device for ease of handling and to minimize disturbance of the subgrade. A minimum dimension should be specified for the rock to aid field inspection. On slopes, uphill boulders should be keyed in below the tops of downhill boulders for stability. A "stairstep" arrangement where the top surface of the rock is flat and horizontal is preferable for both aesthetic and hydraulic reasons.</p>

Table 7.5 (continued)

Type	Quality Concerns	Quality Control Measures and Inspections
Grout	Cement content and type, aggregate and water content are important considerations for strength and durability. Synthetic fibers can be added to the concrete mix, to provide additional crack control and durability.	The key to success with grouting is to use rock that is no smaller in any dimension than the desired grout thickness (so that one can fully access and fill the voids), to pump and place the grout using a grout pumper with a nozzle that can penetrate to the subgrade, to vibrate using a "pencil vibrator" to assure complete filling of the voids, to have good control of the grout mix (too wet creates shrinkage cracks and stability problems on slope; too dry leads to poor penetration), and to place the grout to the desired thickness. A minimum grout thickness is needed to counteract uplift forces. However, placing too much is unattractive and reduces the roughness of the drop which is needed to prevent the jump from washing downstream. During grouting, it is important to protect the weep drains. With care, one can avoid getting grout on the top of the rock. Any spillage should be washed off immediately. A wood float leaves a smooth finish, and the "pencil vibrator", which is preferred, will generally leave a satisfactory appearance with some touch-up. Full time inspection is required during grouting, as is periodic inspection during the rock placement depending upon the performance of the contractor and the aesthetic appearance desired.
Sheetpile	Sheetpile comes in many configurations and, in particular, joint details. It requires geotechnical, structural and hydraulic expertise, as well as pile driving experience during construction.	Inspection is required to ensure that piling is driven to the design depth, or keyed into bedrock if required. Underground obstructions can create problems with driving. If piling becomes separated at the joints during installation, excessive subsurface flow can result.
Synthetic Liners	Liners must be flexible and strong enough to allow adjustment to the actual subgrade, and to allow rock placement without significant damage to the liner material.	Subgrade must be well prepared to minimize voids and piping along the smooth surface of the liner. Certificates of conformance to the technical specifications should be provided by the manufacturer. Liners should be spliced only when necessary and placed in accordance with manufacturers instructions.
Seepage Cutoff Soils	Important considerations are: classification and homogeneity of clay soils, placement and compaction techniques.	The subgrade should be inspected and sloped to achieve compaction of the cutoff soils and the adjacent subgrade. In order to use this type of drop structure, the subgrade soil needs to be a clay (CL), as classified by a qualified soils engineer.
Drains	Permeability and gradation of media, reverse filter characteristics and compatibility with in situ materials, pipe and other hydraulic components.	Gradation analysis of in situ materials and proposed filter media are advisable. Fabric materials should be used with caution to insure that plugging will not occur. Piping and valving components should comply with specifications and be double checked for suitability for the particular application. The toe drain and other drains should be placed and protected from contamination, particularly if grout or concrete is placed later.
Cutoffs using Slurry Trench	The homogeneity and stability of the slurry cutoff is critical. The construction techniques to achieve a cutoff to the desired depth and width are also critical.	Practically, cutoffs using slurry trench techniques are more exotic applications and require intensive geotechnical engineering and custom specifications for individual applications. Measures can involve intensive soil testing, density testing of slurry mixtures, tests related to special chemicals and admixtures, and standard concrete and grout testing methods. Besides inspections related to all of the above, site environmental controls are required for slurry mixing and placement, and for disposal of materials displaced during the process.
Architectural and Landscape Items	Coatings are always subject to quality concerns, which are compounded by substrate conditions. Plantings are subject to a wide variety of quality and size.	Landscape and architectural treatments can make a big difference in appearance; take care to work with experienced professionals.

The hydraulic concept involves flow repeatedly encountering obstructions (baffle piers) that are of a nominal height equivalent to critical depth. The excess energy through the drop is dissipated by the momentum loss associated with the reorientation of flow. A minimum of four rows of baffle piers are recommended to achieve control of the flow and maximum dissipation of energy. Guidelines are given for sizing and spacing the blocks. Designing for proper approach velocities is critical to structure performance. One advantage of the baffle chute drop is that it does not require tailwater control.

Typical design consists of upstream transition walls, a rectangular approach chute, a sloping apron of 2:1, or flatter, slope with multiple rows of baffle piers (see Figure 7.11). The toe of the chute extends below grade and is backfilled with loose rock to prevent undermining the structure by eddy currents or minor degradation of the downstream channel. This rock will rearrange to establish a stable bed condition and produce additional stilling action. The structure is effective without tailwater; however, higher tailwater reduces scour at the toe. Grouted and concrete basins have also been used to prevent a standing pool from forming at the transitions to the downstream trickle and main channels. The structure also lends itself to a variety of soils and foundation conditions.

There are fixed costs associated with the upstream wing walls, crest approach section, downstream transition walls and a minimum length of sloping apron (for four baffle rows). Consequently, the baffle chute becomes more economical with increasing drop height.

This design is quite flexible in adaption, once the hydraulic principles are understood. For example, the design has been modified for low drops by locating two rows of baffles on the slope and two rows on a horizontal extension of the chute. Another approach has been to use a flatter chute slope than the usual 2 horizontal to 1 vertical. There are examples where sloping abutments have been used. Other examples include the use of sloping abutments at the crest and chute sides. These drops can be extended at a later date if downstream bed degradation occurs beyond that initially anticipated.

The potential for debris flow must also be considered. Use caution when conditions include streams with heavy debris flow, because the baffles can become clogged between the interstices, resulting in overflow, low energy dissipation, and direct impingement of the erosive stream jet on the downstream channel.

The design performance has been documented for numerous baffled apron drops (USBR 1974). The resulting design precautions generally relate to relatively minor problems, such as erosion protection in adjacent channels, spray above the chute walls, and debris problems. The basic design criteria and modification details are given in Figures 7.12 and 7.13. Remaining structural design parameters must be determined for specific site conditions. The recommended design procedures are discussed on the following pages.

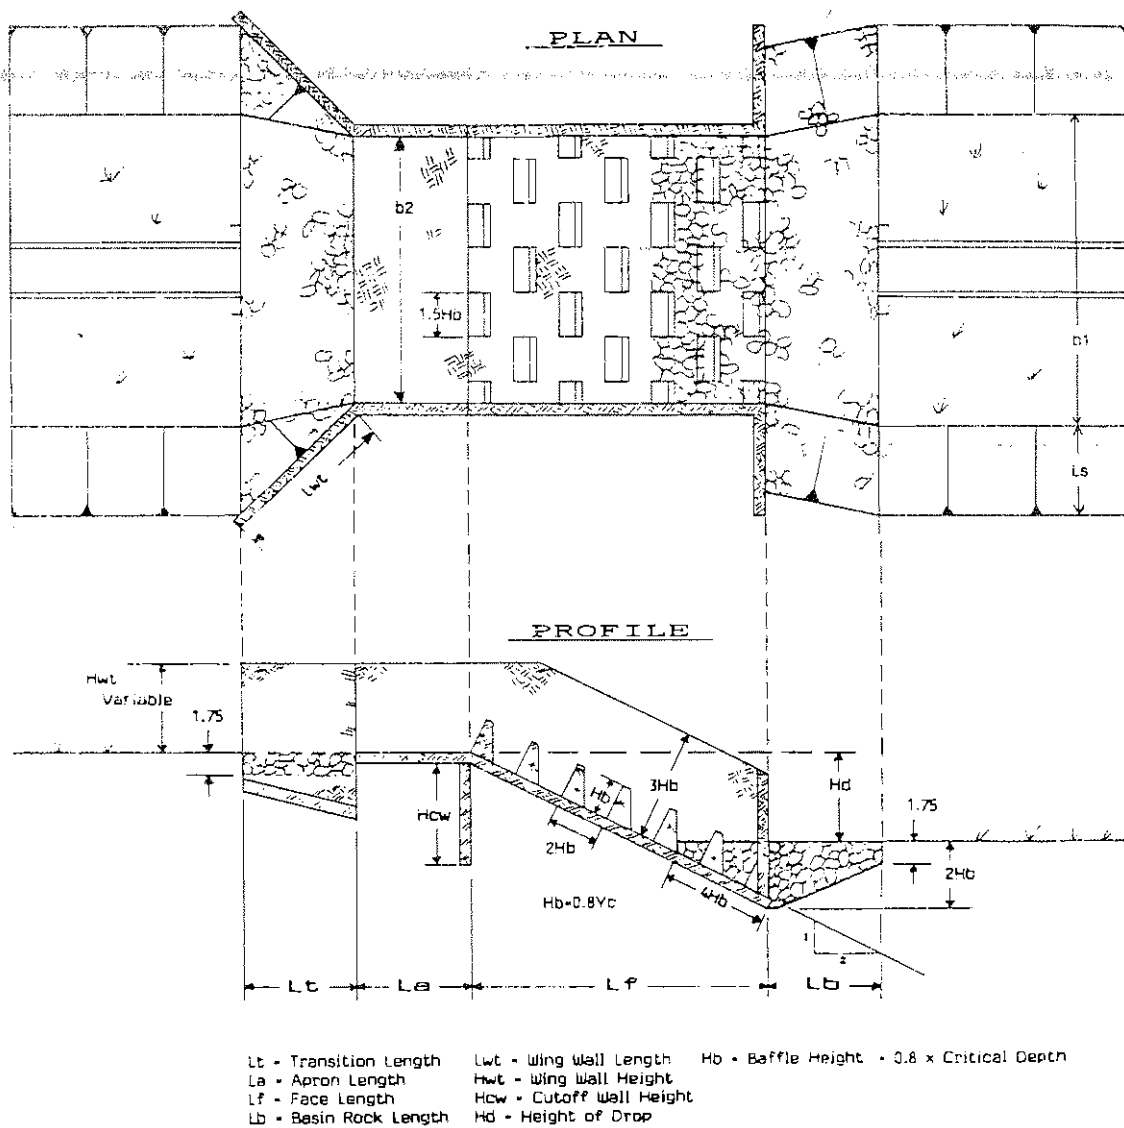

Figure 7.11
Baffle Chute Drop
 (McLaughlin Water Engineers, Ltd., 1986)

General Hydraulic Design Procedure:

1. Determine the maximum inflow rate and the design discharge per unit width:

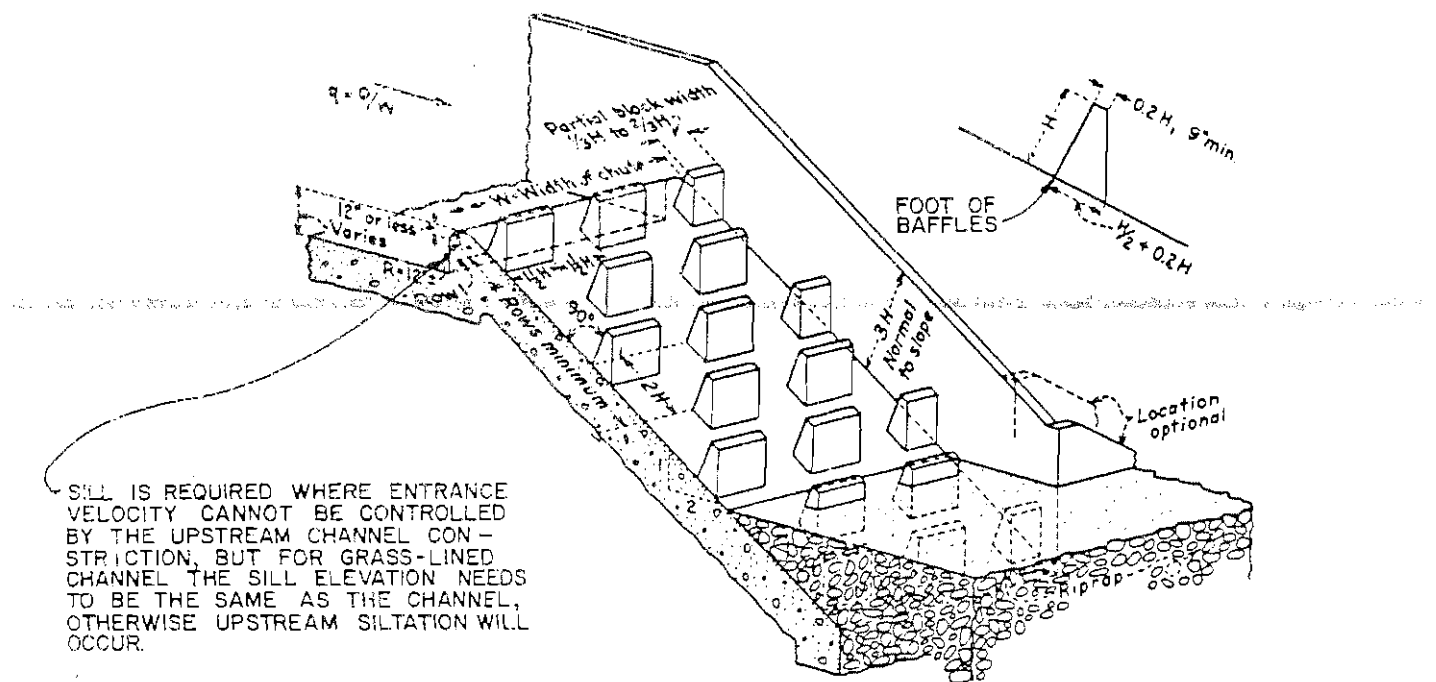

$$q = Q/W \quad (7.6)$$

The chute width, W , may depend on the upstream or downstream channel width, the upstream hydraulic control, economy, or local site topography. Generally, a unit discharge between 35 to 60 cfs/ft is most economical.

2. An upstream channel transition section with vertical wing walls, constructed 45 degrees to the flow direction, causes flow approaching the rectangular chute section to constrict. It is also feasible to use walls constructed at 90 degrees to the flow direction. In either configuration, it is important to analyze the approach hydraulics and water surface profile. Often, the effective flow width at the critical cross section is narrower than the width of the chute opening due to flow separation at the corners of the abutment. To compensate for flow separation, it is recommended that the actual width constructed be 1 foot wider than the design analysis width if the constricted crest width is less than 90 percent of the upstream channel flow width. In any case, the design should carefully consider the approach hydraulics and contraction/separation effects. Depth and approach velocities should be evaluated through the transition to determine freeboard, scour, and sedimentation zones.
3. The entrance transition is followed by a rectangular flow alignment apron, typically 5 feet in length. The upstream approach channel velocity, V , should be as low as practical and less than critical velocity at the control section of the crest. Figure 7.12(b) gives the USBR recommended entrance (channel) velocity. In a typical grass-lined channel, the entrance transition to the rectangular chute section will produce the desired upstream channel velocity reduction. The elevated chute crest above the channel elevation, as shown in Figure 7.12(a), should only be used when approach velocities cannot be controlled by the transition. Special measures to prevent aggradation upstream would be necessary with the raised crest configuration.

Entrance Modification:

1. The trickle flow (or low flow) channel should be maintained through the apron, approach, and crest sections. It may be routed between the first row of baffle piers. The trickle channel should start again at the basin rock zone which should be slightly depressed and then graded up to transition to the downstream channel. Figure 7.13(c) illustrates one method of designing the low flow channel through the crest.

(A) USBR ISOMETRIC

(B) DESIGN CRITERIA

Figure 7.12
Baffle Chute Design Criteria
(Adapted from: Peterka 1984)

Figure 7.13
 Baffle Chute Crest Modifications and Forces
 (Adapted from: Peterka 1984)

2. The conventional design shown in Figure 7.12(a) results in the top elevation of the baffles being higher than the crest, which causes a higher backwater surface effect upstream. Figure 7.12(b) may be used to estimate extent of the effect and to determine corrective measures, such as increasing the upstream freeboard or widening the chute. Note that baffles projecting above the crest will tend to produce upstream sediment aggradation. Channel aggradation can be minimized by the low flow treatment suggested in the previous paragraph.

Another means of alleviating these problems is the Fujimoto entrance, developed by the USBR and illustrated in Figure 7.13(b). The upper rows of baffles are moved one row increment downstream. The important advantage of this entrance is that there is no backwater effect of the baffles. The serrated treatment of the modified crest begins disrupting the flow entering the chute without increasing the headwater. More importantly, this configuration provides a level crest control. The designer may either bring the invert of the upstream low flow channel into this crest elevation, widening the low flow channel as it approaches the crest, or the designer may have a lower trickle channel and bring it through the serrated crest similar to 1, above. These treatments will have to be observed until more application experience shows what may work best.

Structural Design Dimensions:

1. Assume critical flow at the crest and determine critical depth for both peak flow and for 2/3 of peak flow. For unit discharge exceeding 60 cfs/ft, Figure 7.12(b) may be extrapolated:

$$y_c = (q^2/g)^{0.33} \quad (7.7)$$

2. The chute section (baffled apron) is concrete with baffles of height, H_b , equal to 0.8 times critical depth. The chute face slope is 2:1 for most cases, but may be reduced for low drops or where a flatter-slope is desirable. For unit discharge applications greater than 60 cfs/ft, the baffle height may be based on 2/3 of the peak flow; however, the chute side walls should be designed for peak flow (see number 4).

Baffle pier widths and spaces should equal, preferably, about 1.5 H_b but not less than H_b . Other baffle block dimensions are not critical hydraulically. The spacing between the rows of baffle blocks should be H_b times the slope. For example, a 2:1 slope makes the row spacing equal to $2H_b$ parallel to the chute floor. The baffle piers are usually constructed with the upstream face normal to the chute floor surface.

3. Four rows of baffle piers are required to establish full control of the flow, although fewer rows have operated successfully. At least one row of baffles are buried in riprap where the chute extends below the downstream channel grade. Riprap protection continues from the chute outlet to a distance of approximately $4H_b$, or as necessary to prevent eddy currents from undermining the walls. Additional rows of baffles may be buried below grade to allow for downstream channel degradation.

4. The baffle chute side wall height (measured normal to the floor slope) should be 2.4 times the critical depth based on peak discharge (or $3H_b$). The wall height will contain the main flow and most of the splash. The design of the area behind the wall should consider that some splash may occur, but extensive protection measures are not required.
5. Determine upstream transition and apron side wall height as required by backwater analysis. Lower basin wing walls are generally constructed normal to the chute side walls at the chute outlet to prevent eddy current erosion at the drop toe. These transition walls are of a height equal to the channel normal depth plus 1 foot, and length sufficient to inhibit eddy current erosion.
6. All concrete walls and footer dimensions are determined by conventional structural methods. Cutoff walls and underdrain requirements are determined by seepage analysis (see Section 7.3.2.5).
7. The most troublesome aspect of the design is the determination of the hydraulic impact forces on the baffles to allow the structural engineer to size adequate reinforcing steel. Figure 7.13(d) may be used as a guideline. The structural engineer should apply a conservative safety factor, as this curve is based on relatively sparse information.

Construction Considerations: There are numerous steps necessary in the construction of a baffle chute, but they are usually easily controlled by a contractor. For quality control and inspection, there are consistent, measurable, and repeatable standards to apply.

Potential areas of concern include foundation problems, riprap quality control and placement, and finish work with regard to architectural and landscape treatments. Formwork, form ties, and seal coatings can leave a poor appearance, if not handled properly. Poor concrete vibration can result in surface defects (honeycombing) or more serious conditions, such as exposed rebar.

In summary, baffle chute drop structures are the most successful as far as hydraulic performance is concerned and are straight forward to construct. Steel, formwork, concrete placement and finish, and backfill require periodic inspection.

7.3.4.2 Vertical Hard Basin Drops: The vertical hard basin is a generalized category which can include a wide variety of structure design modifications and adaptations. A variety of components can be used for both the hard basin and the wall, various contraction effects can be implemented to reduce approach velocities, and different trickle channel options can be selected.

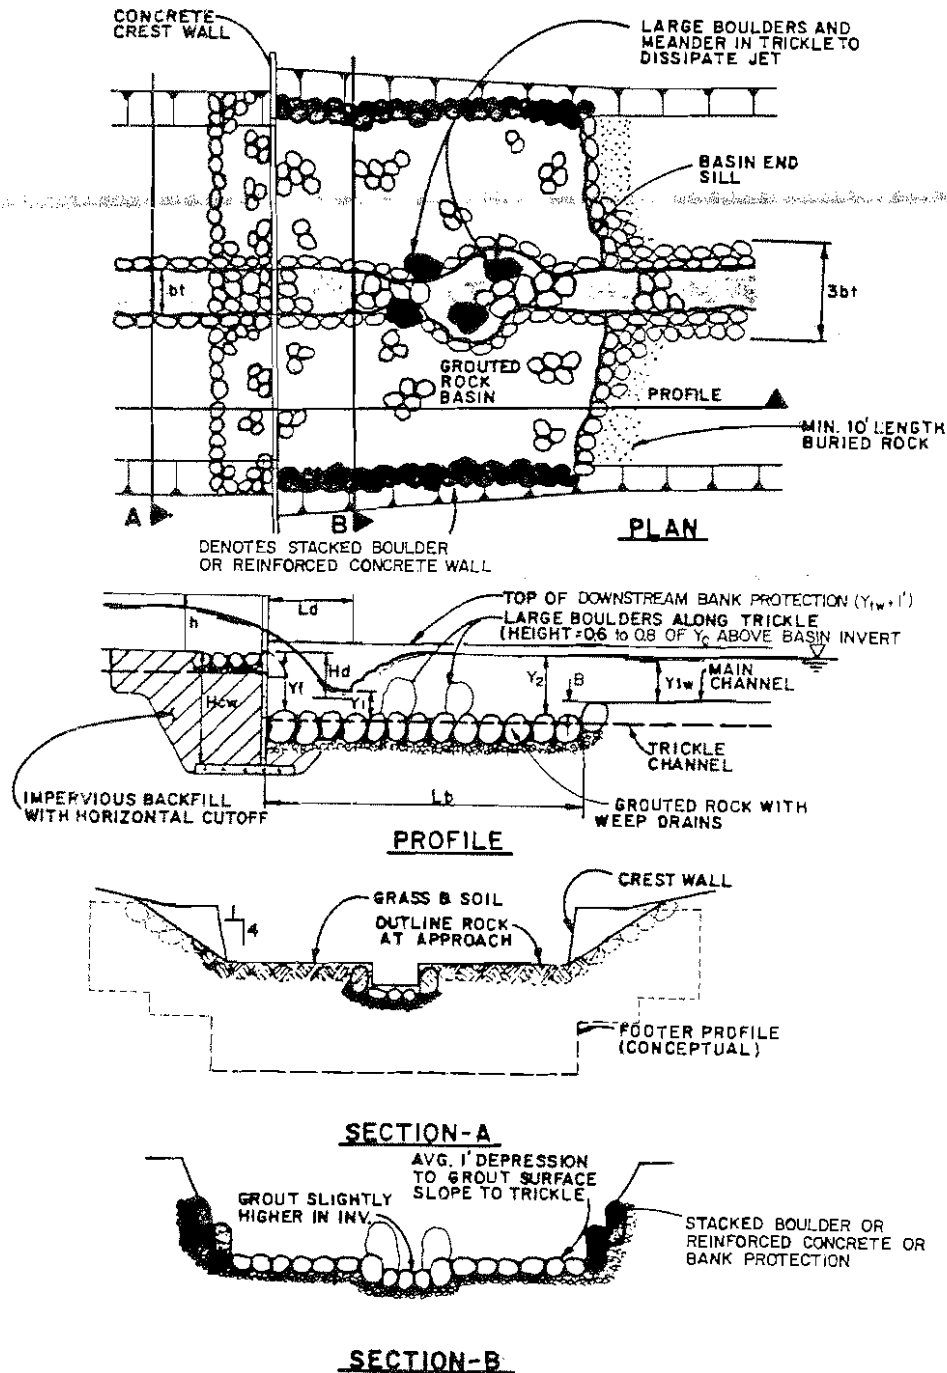

Figure 7.14
Vertical Hard Basin Drop
(McLaughlin Water Engineers, Ltd., 1986)

The maximum vertical drop height from crest to basin for a vertical hard basin drop is limited to 3 feet for safety considerations.

The hydraulic phenomenon provided by this type of drop is a jet of water which overflows the crest wall into the basin below. The jet hits the hard basin and is redirected horizontally. With sufficient tailwater, a hydraulic jump is initiated. Otherwise, the flow continues horizontally in a supercritical mode until the specific force of the tailwater is sufficient to force the jump. Energy is dissipated in the turbulence through the hydraulic jump; therefore, the basin is sized to contain the supercritical flow and the erosive turbulent zone.

Generally, a rough basin is advantageous since increased roughness will result in a shorter, more economical basin. Figure 7.14 shows a vertical drop with a grouted boulder basin (concrete may also be used), and illustrates several important design considerations.

General Hydraulic Design Procedure:

1. The design approach uses the unit discharge in the main channel and the trickle channel to determine the separate water surface profiles and jump locations in these zones. The basin is sized to adequately contain the hydraulic jump and associated turbulent flows.
2. The rock lined approach length ends abruptly at a structural retaining crestwall which has a nearly rectangular cross-section and trickle channel section. (Refer to Section 7.3.2.2.)
3. Crest wall and footer dimensions are determined by conventional structural methods. Underdrain requirements are determined from seepage analysis.
4. *Open Channel Hydraulics* (Chow, 1959), makes a brief presentation for the "Straight Drop Spillway," which applies here. Separate analysis would need to be undertaken for the trickle channel area and the main channel area as discussed in Section 7.3.2.3. In the following equations add the subscript t for the trickle channel area, and the subscript m for the main channel area.

Refer to Figure 7.15 to identify the following parameters. L_b is the design basin length which includes L_d and the distance to the jump, D_j , which is measured from the downstream end of L_d . The jump length, L_j , is approximated as six times the sequent depth, Y_2 . As a safety factor, to assure a sufficient length for L_b , $0.6 L_j$ is added in the design of L_b , such that:

$$L_b \geq L_d + D_j + 9.6 Y_2 \quad (7.8)$$

Figure 7.15
Vertical Drop Hydraulic System
 (McLaughlin Water Engineers, Ltd., 1986)

When a hydraulic jump occurs immediately where the nappe hits the basin floor, the following variables are defined:

$$L_d / Y_f = 4.3 D_n^{0.27} \quad (7.9a)$$

where:

$$D_n = q_c^2 / (g Y_f^3) \quad (7.9b)$$

$$Y_p / Y_f = 1.0 D_n^{0.22} \quad (7.10)$$

$$Y_1 / Y_f = 0.54 D_n^{0.425} \quad (7.11)$$

$$Y_2 / Y_f = 1.66 D_n^{0.27} \quad (7.12)$$

5. In the case where the tailwater does not provide a depth equivalent to or greater than Y_2 , the jet will wash downstream as supercritical flow until its specific force is sufficiently reduced to allow the jump to occur. Determination of the distance to the hydraulic jump, D_j , requires a separate water surface profile analysis for the main and low flow zones. Any change in tailwater affects the stability of the jump in both locations.

6. **Caution is advised regarding the higher unit flow condition in the low flow zone.** Large boulders and meanders in the trickle zone of the basin are shown to help dissipate the jet, and rock is extended downstream along the low flow channel. This results in three possible basin length design conditions:

- a. At the main channel zone:

$$L_{bm} = L_{dm} + D_{jm} + 0.60(6Y_2)_m \quad (7.13)$$

- b. At the trickle zone, standard design:

$$L_{bt} = L_{dt} + D_{jt} + 0.60(6Y_2)_t \quad (7.14)$$

- c. When large boulders or baffles are used to confine the jump to the impingement area of the low flow zone, the low flow basin length may be reduced:

$$L_{bt} = L_{dt} + 0.60(6Y_2)_t \quad (7.15)$$

7. The basin floor elevation is depressed at depth B, variable with drop height and practical for trickle flow drainage. Note that the basin depth adds to the effective tailwater depth. The basin is constructed of concrete or grouted rock. Either material must be evaluated for the hydraulic forces and seepage uplift.
8. There is a sill at the basin end to bring the invert elevation to that of the downstream channel and side walls extending from the crestwall to the sill. The sill is important in causing the hydraulic jump to form in the basin. Buried riprap should be used downstream of the sill to minimize any local scour caused by the lift over the sill.
9. Water surface profile analyses have proven that base widths of the rectangular crest which are less than that of the channel will result in high unit discharges and velocities, thereby requiring unreasonable extensions of both the basin length and

upstream rock protection. Roughness in the basin area can reduce the basin length required to contain the hydraulic jump. This is the primary advantage of the use of grouted rock in the drop basin.

Construction Considerations: Foundation and seepage concerns are very critical with regard to the vertical wall, as poor control can result in sudden failure. The use of caissons or pile can mitigate this effect. Put in comparative terms with the baffle chute, seepage problems can result in displacement of the vertical wall with no warning, where the box-like structure of the baffle chute may evidence some movement or cracking, but not total failure, and thus allow time for repairs.

The quality control concerns and measures for reinforced concrete are described under baffle chutes. The foundation concerns for the wall are critical as described above. The subsoil conditions for the basin are also important so that the basin concrete or grouted riprap is stable against uplift pressures.

A grouted boulder stilling basin provides roughness, which is useful in shortening the basin length. As the name implies, the basin should be constructed of individual boulders placed on a prepared subgrade. Boulders should be a minimum dimension that exceeds the grout layer thickness, so that the contractor and the inspector can see and have grout placed directly to the subgrade and completely filling the voids. Graded riprap should not be used for grouting, as the smaller rock prevents the voids from being completely filled with grout. The result is a direct piping route for water beneath the grout, and a structural slab with insufficient mass. The completed combination of boulders and grout should have an overall weight sufficient to offset uplift forces. A minimum dimension of 18 inches is recommended for boulders, and 12 inches for the grout layer. By maintaining the finished surface of the grout below the top of the boulder, both appearance and roughness characteristics are enhanced. Seepage relief for the basin slab should be provided.

This type of structure has a moderate level of construction difficulty. The wall, once foundation conditions are addressed, is conventional construction. It is very possible for the construction of the seepage control and earthwork to go awry and problems to go undetected until the time of failure. The flat concrete or grouted rock placement is easier for the contractor than graded rock placement/quality control, but again poor placement and undetected subsoil, bedding or rock problems can result in failure. Thus, it is easier than many other types to construct, but susceptible to some hidden risks and problems.

7.3.4.3 Vertical Riprap Basin Drops: As shown in Figure 7.16, this structure is essentially a plunge pool drop that incorporates a reinforced concrete crest wall with a riprap lined dissipation pool below. A nearly rectangular crest section is recommended to reduce the width of the plunge pool.

Maximum drop depth for a vertical riprap basin is limited to 3 feet due to safety considerations and the practicality of obtaining the larger riprap needed for higher drops.

Submergence by high tailwater can limit the dissipation efficiency.

The hydraulic design was developed through model testing by Smith and Strang in 1967 (*Scour in Stone Beds*) and design procedures were further developed by Stevens in 1981 (*Hydraulic Design Criteria for Riprapped Chutes and Vertical Drop Structures*).

In this structure, flow passing over the vertical crest wall plunges into a riprap basin area. Energy is dissipated by turbulence in the plunge pool. Loose riprap is placed in the basin according to the initial design specifications. The rock is successively rearranged by inflows until a more stabilized basin plunge pool is formed. The depth of the scour hole, d_s , and the nominal rock size are inversely related.

Structural design for the vertical crest wall is complicated by the lack of downstream support, seepage, soil saturation and hydraulic loading on the upstream side. In sandy or erosive soils, it is common to use sheet pile for the crest wall construction, while caissons may be an acceptable foundation for certain other applications. A concrete retaining wall is frequently selected for ease of construction, seepage control and low maintenance.

General Hydraulic Design Procedure: The hydraulic analysis of this type of drop is generally similar to that presented in Section 7.3.4.2 for crest hydraulics. The design of the flexible plunge pool basin is described below.

The desired drop across the structure is the difference in the bed elevations of the approach channel at the weir and the downstream channel at the end of the structure. Let this difference be H_d . It follows from Figure 7.16 that:

$$H_d = D - 0.67 d_s \quad (7.16)$$

The designer must find the combination of rock size and jet plunge height D that gives a depth of scour which balances Equation (7.16). The relation between rock size d_{50} , jet plunge height D , head on the weir, H , ($H = 1.5y_c$) and depth of scour d_s is given in Figure 7.17. As these values will be different in the main drop and the trickle, the design d_{50} and/or d_s will vary.

To obtain an adequate cutoff, the depth of the vertical wall that forms the weir crest must extend below the bottom of the excavation for the riprap. Thus, it usually becomes uneconomical to design a scour depth d_s any greater than $0.3D$. To meet this limitation in the field it is necessary to: increase the rock size d_{50} ; decrease the jet plunge height

Figure 7.16
Vertical Riprap Basin Drop
 (Stevens, 1981)

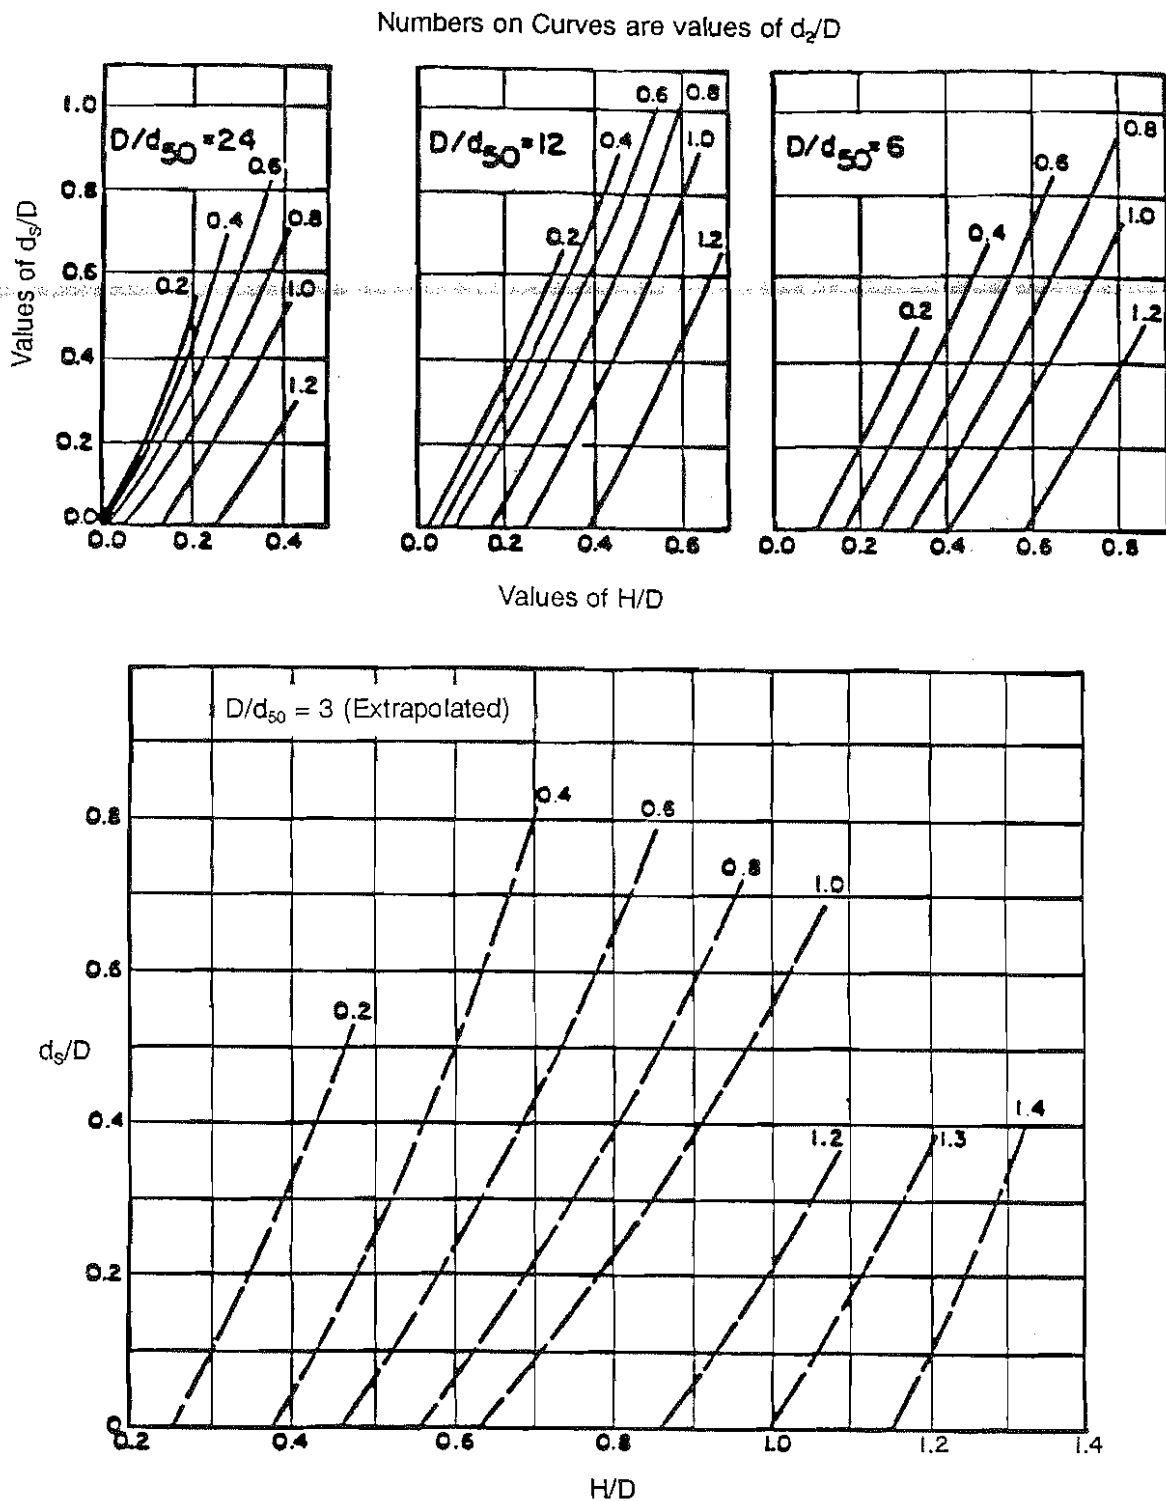

Figure 7.17
Curves for Scour Depth at Vertical Drop
(Stevens, 1981)

D (by using more drops); decrease H (by using a wider structure); or, to use another type of drop structure.

The side slopes in the basin must be riprapped also as there are strong back currents in the basin. Granular filter material is required under this riprap. The side slopes in the basin should be the same slope as for the downstream channel.

Construction Considerations: Foundation and seepage concerns are critical with regard to the vertical wall in this type of drop. They are also generally more critical than with an equivalent vertical drop into a hard basin because the riprap basin may scour and reshape, leaving less supporting material on the downstream side. Thus, if seepage is worse than anticipated, backfill is poor, or if seepage control measures are not functioning, an immediate and severe structure stability problem can occur. The use of caissons or pile can mitigate this effect. Seepage problems can result in displacement of the vertical wall with no cracking as an advance warning. Seepage can also cause piping failure where the water will actually flow under the vertical wall. Problems can result from rock that does not meet specifications for durability, specific gravity or gradation. Quality control of rock installation can be difficult in regard to measuring performance and maintaining consistency. Undersized rock in the plunge pool basin can cause the basin to reshape differently than designed and result in stability problems for the wall, the basin, and the downstream channel.

This type of structure has a moderate level of construction difficulty. The wall, once foundation conditions are addressed, is straight forward. It is very possible for the construction of the seepage control and earthwork to go awry and for problems to go undetected until the time of failure. The flat riprap placement is easier than sloping, but again poor placement and undetected subsoil, bedding, or rock problems can all contribute to failure.

7.3.4.4 Sloping Concrete Drops: The hydraulic concept of these structures is to dissipate energy by formation of a conventional hydraulic jump, usually associated with a reverse current surface flow as the supercritical flow down the face converts to subcritical flow downstream.

Numerous concepts have been investigated. Among them are the Saint Anthony Falls (SAF) Stilling Basin, and the USBR Basins I, II, III, and IV (USDOT, FHWA, HEC-14, 1983; and Peterka 1984). These drops and associated basins are suited for different kinds of situations.

The Saint Anthony Falls Stilling Basin and the USBR Basins (with the exception of Type I) all work at techniques to shorten the basin length. In the USBR Basin I, no special measures are provided. On the smooth concrete basin it can take considerable basin length to "burn off" enough energy to dissipate the supercritical flow of where a jump will begin, and then more length to allow for the turbulence of the jump. Basin I is relatively expensive because of its length. The other basins require a certain amount of tailwater, which requires depressing the basin, and the use of baffles or other shapes to allow shorter basins, related dissipation, and control of troublesome wave patterns.

Figure 7.18 illustrates the various types of stilling basins for use with sloping concrete drops.

General Hydraulic Design Procedure: Design procedures for USBR Basins II, III, and IV and the SAF Stilling Basin are presented in *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983) and *Hydraulic Design of Stilling Basins and Energy Dissipators* (Peterka 1984).

Analysis of channel approach and crest hydraulics generally follows the guidelines presented in Section 7.3.2. Once water surface profiles have been determined, including tailwater determination and supercritical water surfaces down the sloping face, seepage uplift forces must be evaluated. Net uplift forces vary as a function of location along the drop, cutoff measures, drain gallery locations and water surface profiles through the basin.

For a stable structure, net uplift force from seepage must be countered by net forces in the downward direction. For a smooth concrete chute, downward forces are the buoyant weight of the concrete structure and the weight of water (a function of the depth of flow). Significant pressure differentials can occur with a combination of high seepage forces and shallow supercritical flow. Seepage analyses should be conducted using Lane's weighted creep methodology (Section 7.3.2.5), and suitable countermeasures designed. Such measures include cutoff walls, weep drain galleries and concrete slab thickness design. A range of flood discharges should be evaluated, since differential pressure relationships can vary with flow depth and location of hydraulic jump.

Construction Considerations: There may be applications where sloping concrete drops are advantageous, but generally other drops such as baffle chutes or vertical drops are more appropriate for a wider range of applications. The design guidance provided by the literature is clear and relatively easy to use, but the implementation is often difficult or impractical. This basically has to do with providing basin depth without creating a maintenance problem and less flexibility in adapting to varying bed conditions.

The integrity of the cutoff is important as seepage and resultant uplift forces are key concerns. Uncontrolled underflow could easily lift a major concrete slab.

The stilling basin should be designed to drain completely, to eliminate nuisances related to ponded water, such as mosquito breeding and sediment/debris accumulation.

Considerations relating to general concrete construction are the same as discussed previously for baffle chute drops. Public acceptability is likely to be low in urban areas, as the sloping concrete face is inviting for bicyclists, roller skaters, and skateboard enthusiasts.

USBR TYPE III

USBR TYPE IV

SAF STILLING BASIN

Figure 7.18
Stilling Basins for Sloping Concrete Drops
 (Adapted from: USDOT, FHWA, HEC-14, 1983)

7.3.4.5 Other Types of Drop Structures: There are numerous other types of drop structures for specific applications in drainage design. The four types of structures presented above are appropriate for the majority of situations to be encountered in Maricopa County. Some possible variations or modifications are presented below along with a few specialized types.

Sloping Drop Variations: The use of soil cement, roller compacted concrete, and grouted boulders are possible variations in sloping drop design. The primary concern with soil cement is its ability to resist the high abrasive action of turbulent flow associated with a drop structure. Adequate countermeasures would be required to demonstrate the suitability of soil cement prior to its approval for use on drop structures.

Addition of roughness elements on the face of a sloping concrete drop can provide increased energy dissipation. "Stepped" concrete has been successfully applied at spillways and drop structures. Roller compacted concrete is a methodology that can achieve the stairstep geometry on the face of a sloping drop. Reinforced concrete steps can be constructed by standard construction methods on small structures.

Construction of a drop with grouted boulders is another means of creating desirable roughness on the sloping face and in the stilling basin (see Figure 7.19).

However, because the structure is comprised of a structural slab with two components (boulders and grout), great care must be taken to design the structure to withstand uplift and to specify boulder and grout material to assure full quality control in the field. Seepage analysis is required to determine a compatible combination of cutoff depth, location of the toe drain and/or other drains, and the thickness of rock and grout. Problems with rock specific gravity, durability and hardness are of concern. Gradation problems are largely eliminated because the boulders are specified to meet minimum physical dimensions and/or weights, which is much easier to observe and enforce in the field than with graded riprap.

The handling of the large boulders requires skilled work force and specialized equipment. Equipment similar to logging tongs, and specially modified buckets with hydraulically powered "thumbs" have been used in recent years and have greatly improved quality and placement rates. The careful placement of stacked boulders, so that the upstream rock is keyed in behind the downstream rock, and placed with a large flat surface horizontally, has been shown to be successful.

The greatest danger lies with a "sugar coated" grout job, where the grout does not penetrate the voids between the rock and the subgrade, leaving a direct piping route for water under the grout. This can easily occur when attempting to grout graded riprap, thus the need to use individual boulders that are larger in diameter than the grout layer so that the contractor and the inspector can see and have grout placed directly to the subgrade. The best balance appears to be boulders 33 to 50 percent greater in size than the grout thickness, but of an overall weight sufficient to offset uplift. Also, when holding grout to this level, the appearance will be much better.

NOTES:

- 1) CLEAN ALL DIRT FROM VOIDS BEFORE GROUTING.
- 2) PLACE BOULDERS WITH FLATTEST SURFACE ON TOP AND HORIZONTAL. PLACE BOULDERS IN INTERLOCKING FASHION, TOUCHING ADJACENT BOULDERS AND MINIMIZING VOIDS.
- 3) DEPTH OF ROCK (D_r) AND DEPTH OF GROUT (D_g) AS CALLED OUT ON PLANS.
- 4) GROUT TO PENETRATE FULL DEPTH OF ROCK AND FILL ALL VOIDS.
- 5) CLEAN ALL GROUT FROM EXPOSED SURFACES.
- 6) GRAVEL GALLERIES ARE CALLED OUT ON PLANS AS "W" (width of gallery) GRAVEL GALLERY (ies) "S" (spacing between galleries) O.C.

Figure 7.19
Grouted Boulder Placement
(McLaughlin Water Engineers, Ltd., 1986)

The grout should have a minimum 4,000 psi compressive strength at 28 days, stone aggregate with a maximum dimension of one-half inch and a slump within a range of 4 to 7 inches. The water/cement ratio should not exceed 0.48. Addition of synthetic fiber reinforcement is also recommended to provide crack control, increased durability, and increased abrasion resistance.

Other USBR Basins: Some other stilling basins developed by the USBR (Peterka 1984) have limited application. For example, Basin I is basically a horizontal concrete apron downstream of a sloping or vertical drop. This type of basin is applicable only to a concrete lined channel, and, as the USBR states, has wave problems that are difficult to overcome. Maintenance of sufficient tailwater depth is important to cause a hydraulic jump within a practical zone close to the toe of the drop. Generally, other types of USBR basins are better alternatives to Basin I.

Figure 7.20
Box Inlet Drop Structure
(Adapted from: FHWA, HEC-14, 1983)

USBR Basin V is a stilling basin with sloping apron, and provides dissipation as effective as that which occurs in the basin with a horizontal apron. Again, adequate tailwater is a must. This type of structure would have an application as a spillway into a pond with a permanent pool, so that minimum tailwater is essentially guaranteed.

Box Inlet Drop Structure: The box inlet drop structure may be described as a rectangular box open at the top and downstream end (Figure 7.20). Water is directed to the crest of the box inlet by earth dikes and headwalls. A flow enters over the upstream end and two sides and leaves the structure through the open downstream end. The long crest of the box inlet permits large flows to pass at relatively low heads. The width of the structure does not need to be greater than the downstream channel. It is applicable for drops from 2 feet to 12 feet.

The outlet structure can be adjusted to fit a wide variety of field conditions. It is possible to lengthen the straight section and cover it to form a highway culvert. The sidewalls of the stilling basin section can be flared if desired, thus permitting use with narrow channels or wide floodplains. Flaring the sidewalls also makes it possible to adjust the outlet depth to match the natural channel.

Design guidelines are presented in *Hydraulic Design of Energy Dissipators for Culvert and Channels* (USDOT, FHWA, HEC-14, 1983).

7.3.4.6 Low Flow Check Structures: Low flow check structures and associated erosion control techniques can be effective in stabilizing natural channels and other unlined channels. With the advent of floodplain management and regulation, private developers are frequently directed to preserve the floodplain. Unfortunately, urbanization creates more frequent and sustained flows. The overall floodplain may remain relatively stable, but the low flow channel becomes more susceptible to erosion.

Stream stabilization of base flow channels involves determination of the stable slope and configuration for a variety of frequent runoff rates, with particular emphasis on the dominant discharge (mean annual flood). Local soils, bed materials, and sediment gradation must be considered.

Low flow check structures are designed to provide control points and establish/maintain stable bed slopes within the base flow channel. Other options include low flow (trickle) channel lining, toe riprap, control sills across the floodplain, revetments, and groins.

Check structures are frequently submerged during higher flood events. The application and sizing is complex because of the need to address a wide range of flows. Although the checks may stabilize the channel for low flows, they may be in jeopardy from mid- to high-range flows as water goes around the check abutments. Extensive care is needed with seepage cutoff and abutments that key far back into areas that are less likely to be damaged during high flows. Care should be taken to have a depressed stilling area to avoid a secondary drop at the end to the drop. In any case, ongoing maintenance of check structures will be likely and should be considered in the design so later repairs are practicable.

7.4 Conduit Outlet Structures

7.4.1 General

Concrete energy dissipation or stilling basin structures are required to prevent scour damages caused by high exit velocities and flow expansion turbulence at conduit outlets.

Outlet structures can provide a high degree of energy dissipation and are generally effective even with relatively low tailwater control. Rock protection at conduit outlets is appropriate where moderate outlet conditions exist; however, there are many situations where rock basins are impractical even at low to moderate flow conditions. Concrete outlet structures can be designed easily and are suitable for a wide variety of site conditions. In some cases, they are more economical than large rock basins, particularly where long term costs are considered.

7.4.2 Riprap Protection at Conduit Outlets

7.4.2.1 General Operating Characteristics: A stilling basin constructed of loose, graded riprap can be an effective and economical energy dissipation measure for a conduit outlet. *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983), contains a design procedure for riprap energy dissipators based on studies conducted at Colorado State University and sponsored by the Wyoming Highway Department. The following conclusions were drawn from an analysis of the experimental data and observed operating characteristics.

- » The depth (h_s), length (L_s), and width (W_s) of the scour hole were related to the characteristic size of riprap (d_{50}), discharge (Q), brink depth (Y_o), and tail water depth (TW).
- » The dimensions of a scour hole in a basin constructed with angular rock were approximately the same as those of a scour hole in a basin constructed of rounded material when rock size and other variables were similar.
- » When the ratio of tailwater depth to brink depth (TW/Y_o) was less than 0.75 and the ratio of scour depth to size of riprap (h_s/d_{50}) was greater than 2.0, the scour hole functioned very efficiently as an energy dissipator. The concentrated flow at the culvert brink plunged into the hole, a jump formed against the downstream extremity of the scour hole, and flow was generally well dispersed as it left the basin.
- » The mound of material which formed on the bed downstream of the scour hole contributed to the dissipation of energy and reduced the size of the scour hole; i.e., if the mound from a stable scoured basin was removed and the basin was again subjected to design flow, the scour hole enlarged somewhat.

- » For high tailwater basins ($TW/Y_o > 0.75$) the high velocity core of water emerging from the culvert retained its jet-like character as it passed through the basin, and diffused in a manner very similar to that of a concentrated jet diffusing in a large body of water. As a result, the scour hole was much shallower and generally longer. Consequently, riprap may be required for the channel downstream of the rock-lined basin.

General details of the basin are shown in Figure 7.21, and the principal features are:

- » The basin is preshaped and lined with riprap of median size d_{50} .
- » The surface of the riprapped floor of the energy dissipating pool is constructed at an elevation, h_s , below the culvert invert. Elevation h_s is the approximate depth of scour that would occur in a thick pad of riprap of size d_{50} constructed at the outfall of the culvert if subjected to design discharge. The ratio of h_s to d_{50} of the material should be between 2 and 4.
- » The length of the energy dissipating pool, L_s , is $10 h_s$ or $3W_o$ whichever is larger. The overall length of the basin, L_b , is $15 h_s$ or $4W_o$ whichever is larger.

7.4.2.2 General Hydraulic Design Procedure:

1. Estimate the flow properties at the brink of the culvert. Establish the brink invert elevation such that $TW/Y_o \leq 0.75$ for design discharge.
2. For subcritical flow conditions (culvert set on mild or horizontal slope), use Figure 7.22 or Figure 7.23 to obtain Y_o/D , then obtain V_o by dividing Q by the wetted area associated with Y_o . D is the height of a box culvert. If the culvert is on a steep slope, V_o will be the normal velocity obtained by using the Manning equation for appropriate slope, section, and discharge.
3. From site inspection and from field experience in the area, determine whether or not channel protection is required at the culvert outlet.
4. If the channel protection is required, compute the Froude number for brink conditions ($y_e = (A/2)^{1/3}$ for non-rectangular culverts). Select d_{50}/y_e appropriate for locally available riprap (usually the most satisfactory results will be obtained if $0.25 < d_{50}/y_e < 0.45$). Obtain h_s/y_e from Figure 7.24, and check to see that $2 < h_s/d_{50} < 4$. Recycle computations if h_s/d_{50} falls out of this range.
5. Size basin as shown in Figure 7.21.

Figure 7.22

 Dimensionless Rating Curves for the Outlets of Circular Culverts
 on Horizontal and Mild Slopes
 (Simons, et al, 1970)

Figure 7.24
Relative Depth of Scour Hole versus Froude Number at Brink of Culvert
with Relative Size of Riprap as a Third Variable
(USDOT, FHWA, HEC-14, 1983)

6. Design procedures where allowable dissipator exit velocity is specified:

- » Determine the average normal flow depth in the natural channel for the design discharge.
- » Extend the length of the energy basin (if necessary) so that the width of the energy basin (at Section A-A, Figure 7.21), times the average normal flow depth in the natural channel is approximately equal to the design discharge divided by the specified exit velocity.

7. In the exit region of the basin, the walls and apron of the basin should be warped (or transitioned) so that the cross section of the basin at the exit conforms to the cross section of the natural channel. Abrupt transition of surfaces should be avoided to minimize separation zones and resultant eddies.

Figure 7.25

Distribution of Centerline Velocity for Flow from Submerged Outlets

(To be used for predicting channel velocities downstream from culvert outlets where high tailwater prevails)
(Simons, et al, 1970; and USDOT, FHWA, HEC-14, 1983)

8. If high tailwater is a possibility and erosion protection is necessary for the downstream channel, the following design procedure is suggested:

Design a conventional basin for low tailwater conditions in accordance with the instructions above. Estimate centerline velocity at a series of downstream cross sections using the information shown in Figure 7.25. Shape downstream channel and size riprap using guidelines presented in Chapter 6 and the stream velocities obtained above.

Additional information regarding design of riprap basins for conduit outlets may be found in *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983).

7.4.3 Concrete Outlet Structures

This section provides hydraulic concepts and design criteria for an impact stilling basin and adaptation of a baffled apron to conduit outlets. Initial design selection should include at least the following aspects concerning conduit outlet structures.

1. High energy dissipation efficiency is required - hydraulic conditions exceed the limits for alternate designs (such as riprap outlet protection).
2. Low tailwater control is anticipated. For example, at outfalls to detention/retention facilities that are empty or have low water levels.
3. Use of concrete is more economical due to structure size or local availability of materials.
4. Site conditions direct the use of an outlet structure such as public use areas where plunge pools and standing water are unacceptable or locations with severe space limitations.

7.4.3.1 Impact Stilling Basin: Design standards are based on the USBR Type VI Basin, commonly referred to as an impact dissipator or conduit outlet stilling basin. The Type VI Basin is a relatively small structure which produces highly efficient energy dissipation characteristics without tailwater control. The original hydraulic design reference is *Hydraulic Design of Stilling Basins for Pipe or Channel Outlets* (Peterka, 1984). Additional structural details are provided in *Design of Small Canal Structures* (USBR, 1974).

The structure is designed to operate continuously at the design flow rate. Maximum entrance conditions are up to 50 feet per second velocity and Froude number less than 9.0. Conditions exceeding this criteria would be extremely rare in typical urban drainage applications. As a result, the use of this outlet basin is limited only by structural and economic considerations.

Energy dissipation is accomplished through momentum transfer as flow entering the basin impacts a large overhanging baffle. At high flow, further dissipation is produced as water builds up behind the baffle to form a highly turbulent backwater zone. Flow is then re-directed under the baffle to the open basin and out to the receiving channel. A sill at the basin end reduces exit velocities by breaking up the flow across the basin floor and improves the stilling action at low to moderate flow rates. A notch is recommended in end sills to provide for low flow drainage.

The generalized design configuration (Figure 7.26) consists of an open concrete box attached directly to the conduit outlet. The side walls are high enough to contain most of the splashing during high flows and slope down to form a transition to the receiving channel. The inlet pipe is vertically aligned with an overhanging L-shaped baffle such that the pipe invert is not lower than the bottom of the baffle. The end sill height is equal to the height under the baffle to produce tailwater in the basin. The alternate and transition (at 45 degrees) is recommended for grass lined channels to reduce the overall scour potential just downstream of the sill.

The standard USBR design has been modified for urban applications to allow drainage of the basin bottom during dry periods. The impact basin can also be adapted to multiple pipe installations. These modifications are discussed following the basic criteria. It should be noted that modifications to the design may affect the hydraulic performance of the structure. Model testing is advised for significant changes to the design.

General Hydraulic Design Procedure for Stilling Basins:

1. Determine the design pipe flow rate Q and the effective flow area A at the outlet. For partial flow conditions, refer to the partial flow diagram in Section 7.3. Using the relationship $Q = AV$, determine the flow velocity V at the pipe outlet. Assume depth $D = A^{0.5}$ and compute the Froude number $= V/(gD)^{0.5}$.
2. The entrance pipe should be turned horizontal at least one pipe diameter equivalent length upstream from the outlet. For pipe slopes greater than 15 degrees, the horizontal length should be a minimum of two pipe diameters.
3. Do not use this type of outlet energy dissipator when exit velocities exceed 50 feet per second or Froude numbers exceed 9.0. These conditions would be extreme and must be considered as special cases. Performance is achieved with a tailwater depth equal to half full flow level in the pipe outlet.
4. Determine the basin width (W) by entering the appropriate Froude number and effective flow depth on Figure 7.27. The remaining dimensions are proportional to the basin width according to the legend in Figure 7.26. Note that the baffle thickness, t , is a suggested minimum. It is not a hydraulic parameter and is not a substitute for structural analysis.

The basin width should not be increased since the basin is inherently

Figure 7.26
General Design of the USBR Type VI Impact Stilling Basin
(Adapted from: Peterka 1984)

"W" is the inside width of the basin.

"D" represents the depth of flow entering the basin and is the square root of the flow area at the conduit outlet.

"V" is the velocity of the incoming flow.

The tailwater depth is uncontrolled.

Figure 7.27
Design Width of the USBR Type VI Basin
 (Adapted from: Peterka, 1984)

oversized for less than design flows. Larger basins become less effective as the inflow can pass under the baffle.

5. Structure wall thickness, steel reinforcement, and anchor walls (underneath the floor) should be designed using accepted structural engineering methods. Hydraulic forces on the overhanging baffle may be approximated by determination of the jet momentum force:

$$F_m = \rho VQ = 1.94VQ \quad (7.17)$$

6. Riprap with a minimum D_{50} of 18 inches should be provided in the receiving channel from the end sill to a minimum distance equal to the basin width. The depth of rock should be equal to the sill height or at least 2.5 feet. Rock may be buried below finished grades and the area vegetated as desired to match the site.
7. The alternate end sill and wingwall shown in Figure 7.26 is recommended for all grass lined channels to reduce the scour potential below the sill wall.

Low Flow Modifications: The standard design will retain a standing pool of water in the basin bottom which is generally undesirable from a safety and maintenance standpoint. This situation should be alleviated where practical by matching the receiving channel low flow depth to the basin depth, see Figure 7.28.

A low flow gap is extended through the basin end sill wall. The gap in the sill should be as narrow as possible to minimize effects on the sill hydraulics. This implies that a narrow and deeper (1.5 to 2-foot) low flow channel will work better than a wider gap section. The low flow width should not exceed 60 percent of the pipe diameter to prevent the jet from short-circuiting through the cleanout notches.

Low flow modifications have not been fully tested to date. Caution is advised to avoid compromising the overall hydraulic performance of the structure. Other ideas are possible including locating the low flow gap at one side (off center) to prevent a high velocity jet from flowing from the pipe straight down the low flow channel.

The optimal configuration results in continuous drainage of the basin area and helps to reduce the amount of sediment entrapment.

1. For large basins where the sill height is greater than 2.0 feet, the depth dimension, d , (in Figure 7.26) may be reduced to avoid a secondary drop from the sill to the main channel. The low flow invert thereby matches the floor invert at the basin end and the main channel elevation is equal to the sill. Dimension d should not be reduced by more than one-third and not less than 2 feet. This implies that a deeper low flow channel (1.5 to 2.0 feet) will be advantageous for these installations.

Figure 7.28
Modifications to Impact Stilling Basin
(To Allow Basin Drainage for Urban Applications)
(McLaughlin Water Engineers, Ltd., 1986)

Note that dimension d is also reduced at the minimum pipe invert height and at the bottom of the baffle wall.

2. A sill section should be constructed directly in front of the low flow notch to break up bottom flow velocities. The length of this sill section should overlap the width of the low flow by about 1 foot. The general layout for the low flow modifications is shown in Figure 7.28.

Multiple Conduit Installations: Where more than one conduit of different sizes has outlets in close proximity, a composite structure can be constructed to take advantage of common walls. This can be somewhat awkward since each basin "cell" must be designed as an individual basin with different dimensions. Where two conduits of the same size have close outlets, the structures may be combined into a single basin as shown in Figure 7.28.

The total width of a combined dual inlet basin can be reduced to three-fourths of the total width for separate basins. For example, if the design width for each pipe is W , the combined basin width would be $1.5W$.

The effect of mixing and turbulence of the combined flows in the basin has not been model tested to date. It is suggested that no wall be constructed to separate flow behind the baffle, thereby allowing greater turbulence in the combined basin.

Remaining structure dimensions are based on the design width of a separate basin W . If the two pipes have different flows, the combined structure should be based on the higher Froude number flows.

7.4.3.2 Baffle Chute Energy Dissipator: The baffle chute developed by Peterka (1984) has also been adapted to use at pipe outlets. This structure is particularly well suited to situations with very large conduit outfalls and at outfalls to channels in which some future degradation is anticipated. As mentioned previously, the apron can be extended at a later time to account for channel subsidence. Generally, this type of structure is only cost effective if a grade drop is necessary below the outfall elevation and a hydraulic backwater can be tolerated in the culvert design.

Figure 7.29 illustrates a general configuration for baffled outlet for a double box culvert outlet. In this case, an expansion zone occurs just upstream of the approach depression. The depression depth is designed as required to achieve the flow velocity at the chute entrance as described in Section 7.3.4.1. The remaining hydraulic design is the same as for a standard baffle chute. The same crest modifications are applicable to allow drainage of the approach depression, to reduce the upstream backwater effects of the baffles, and to reduce the problems of debris accumulation at the upstream row of baffles.

An effective means of controlling velocities within the culvert is the use of reinforced concrete pipe (RCP) velocity control rings. The culvert velocity reduction by internal energy dissipators (velocity control rings or roughness elements) force the hydraulic

 (Adapted from: Peterka, 1984)

jump to occur within the culvert, thus eliminating costly outlet structures. The design procedures can be found in *Concrete Pipe Handbook* (ACPA, 1988) and HEC-14 (USDOT, FHWA, 1983).

7.5 Special Channel Structures

7.5.1 Channel Transitions

A flow transition is a change of the open channel flow cross section designed to be accomplished in a short distance with a minimum amount of flow disturbance. Types of transitions are illustrated in Figure 7.30. Of these, the abrupt (headwall) and the straight line (wingwall) are the most common.

Specially designed open channel flow transitions (contractions) are normally not required for highway culverts. A culvert is normally designed to operate with an upstream headwater pool which dissipates the channel approach velocity and, therefore, negates the need for an approach flow transition. The side and slope tapered inlets for culverts are also designed primarily as submerged transitions and are discussed in Chapter 5.

Special inlet transitions are useful when the conservation of flow energy is essential because of allowable headwater consideration such as an irrigation structure in subcritical flow, or where it is desirable to maintain a small cross section with supercritical flow in a steep channel.

Outlet transitions (expansions) must be considered in the design of all culverts, channel, protection, and energy dissipators. Design considerations for subcritical channel transitions are presented in *Hydraulic Design of Energy Dissipators for Culverts and Channels* (USDOT, FHWA, HEC-14, 1983)

7.5.2 Supercritical Flow Structures

7.5.2.1 Acceleration Chutes: Acceleration chutes, whether leading into box culverts, pipes, or high velocity open channels, are often used to reduce downstream cross sections, hence, reducing costs. Chute spillways may be used in connection with both off-stream and on-stream detention reservoirs for a control structure and/or a spillway.

Acceleration chutes are potentially hazardous if inadequately planned and designed (see USBR 1974; Peterka 1984; and SCS 1976). High velocity flow can wash out channels and structures downstream in short order, resulting in property damage and uncontrolled flow.

Figure 7.30
Channel Transition Types
(Adapted from: USDOT, FHWA, HEC-14, 1983)

The references cited previously address acceleration chutes in greater detail than can be discussed in this manual. Refer to these publications for a detailed analysis.

Chutes have four component parts:

1. Inlet
2. Vertical Curve Section
3. Concrete, Steeply Sloped Channel
4. Outlet

Several types of inlets can be incorporated depending on the physical conditions and the type of control desired, particularly when using chute spillways for off-stream detention facilities. The types of inlets to be considered are:

- Straight Inlet
- Box Inlet
- Side-Channel Inlet
- Culvert Inlet
- Drop Inlet

Normally, the flow must remain at supercritical through the length of the chute and into the channel or conduit downstream. Care must be exercised in the design to insure against an unwanted hydraulic jump in the downstream channel or conduit. The analysis must include computation of the energy gradient through the chute and in the downstream channel or conduit.

7.5.2.2 Bends: Structures are generally unnecessary in subcritical flow channels unless the bend is of small radius. Structures for supercritical flows are complex and require careful hydraulic design to control the flow.

Bends are normally not used in supercritical flow channels because of the costs involved and the hazards introduced. It is possible to utilize banking, easement curves, and diagonal sills (Knapp, 1951). Sometimes outside bank rollover structures might even be considered. All of these, however, are generally out of place in urban drainage works. Additional design guidelines for open channel bends may be found in *Hydraulic Design of Flood Control Channels* (USACE, 1991).

When a bend is necessary, and it is not practical to first take the flow into subcritical flow, the designer will generally conclude that the channel should be placed in the closed conduit for the entire reach of the bend, and downstream far enough to eliminate

the main oscillations. A model test is usually required on such structures. Furthermore, the forces exerted on the structure are large and must be analyzed.

The forces involved with hydraulic structures are large, and their analyses are often complex. The forces created can cause substantial damage if provisions are not made for their control. In bends, forces are usually larger than what is intuitively assumed. The momentum equation permits solution for the force acting upon the flow boundary at a bend.

$$F_b = M\Delta V \quad (7.18)$$

where Δv represents the change in direction and/or magnitude of the velocity through the section bend.

The force due to pressure on the bend should also be calculated when conduits flow under pressure.

$$\Delta P = \frac{P}{2}(\Delta V^2) \quad (7.19)$$

where ΔP represents the pressure change caused by the difference in the squares of the velocities through the bend. The total exerted force on the bend by the water, the total of momentum and pressure forces, must be counteracted by external forces. Allowable soil bearing should be determined using soil tests if necessary. Forces which cannot be handled by conduit bearing on the soil must be compensated for by additional thrust blocks or other structures.

7.6 Safety

Hydraulic structures constructed in Maricopa County will usually be subject to public access.

Designs for hydraulic structures must address the issue of safety. First, signage must be provided to identify the potential hazard of flooding or dangerous flow measures to the public. Second, appropriate measures must be designed to keep the public away from hazardous locations. For example, vertical drop structures should not exceed 3 feet in height, and adequate fencing or railings must be provided along all other walls, such as wing walls or training walls.

Additional considerations for safety are discussed in Chapter 5.

7.7 Operation, Maintenance and Aesthetic Considerations

7.7.1 Operation and Maintenance

Hydraulic structures should be designed so they can be maintained. As with other drainage facilities, maintenance operations will consist of scheduled and unscheduled operations. Scheduled operations include mowing, debris removal, graffiti removal, and rock replacement. Unscheduled operations are those which follow a storm event and include debris removal, rock replacement, erosion repair, fence or railing repair and other activities for which the frequency and scope cannot be predicted. Some maintenance considerations appropriate for hydraulic structures are presented below. Access to key areas (i.e. crest area, stilling basin area) for maintenance equipment and personnel is the primary consideration common to all structure types.

A 4:1 slope is recommended as a minimum for mowing equipment on landscaped or grass bank and transition slopes. The local jurisdictional agency should be consulted regarding special circumstances for specific site constraints where a steeper slope may be necessary.

Transition areas upstream and downstream of the structures should be designed to drain completely. This applies particularly to stilling basins.

Selection and placement of rock for a stilling basin or upstream of a drop crest should consider a size range not easily displaced by flow as well as one not easily moved by vandalism. Grouted boulders are a suitable alternative.

Open channels are recommended in lieu of pipes for conveyance of low flows through the drop structure area. Pipes may plug or frequently overtop, leading to additional maintenance problems. Pipes should be no smaller than 24 inches in diameter.

Riprap should be provided at likely scour areas that are relatively expensive to access and repair later.

7.7.2 Structure Aesthetics

7.7.2.1 General: Aesthetics, safety, recreation, and overall integration with nearby land uses are important aspects in the design of hydraulic structures. The design and planning, construction, and maintenance of hydraulic structures and natural drainageways in an urban setting all offer opportunities for promoting aesthetic design and habitat features. Maximizing functional uses while improving visual quality requires good planning from the onset of the project, and the coordinated efforts of the owner/client, engineer, landscape architect, and planner.

The significance of providing an aesthetic and visually appealing project depends on the number, type, and frequency of viewer; the viewing angle; project location; and the overall environment of the project area. Aesthetic considerations are site and project specific.

The combination and diversity of forms, lines, colors, and textures create the visual experience. Material selection and landscape design can provide visual character and create interesting spaces in and around hydraulic structures.

7.7.2.2 Open Spaces and Parks: Creative planning concepts in urban and urbanizing areas, particularly in residential areas, emphasize multiple uses of flood control, recreation, and open spaces. Cluster housing and good subdivision planning may be coordinated to offer opportunities to maintain the natural habitat characteristics of the drainageway while fulfilling open space and recreation requirements.

Multiple use of flood control structures and open space parks has proven to be an effective and aesthetic land use combination. Athletic fields and detention areas which remain dry most of the time have been used in many communities. The design of overflow structures and crest controls can be combined with concrete pathways to blend with a park lined environment.

7.7.2.3 Materials: A variety of materials and finishes are available for use in hydraulic structures. Concrete color additions, exposed aggregates and form liners can be used to create visual interest to otherwise stark walls. The location of expansion and control joints in combination with reveals can be used to create effective design detailing of headwalls and abutments. Rock and vegetation can be used for bank stability and erosion protection around structures to provide visual contrast and diversity, and spatial character.

7.8 Design Examples for Riprap Basins

7.8.1 Design Example Number 1

Given:

8 ft by 6 ft box culvert
 $Q = 800$ cfs
 supercritical flow in culvert
 normal flow depth = brink depth
 $Y_o = 4$ ft
 Tailwater depth (TW) = 2.8 ft

Find:

Riprap basin dimensions for these conditions.

Solution:

1. $Y_o = y_e$ for rectangular section, $y_e = 4$ ft
2. $V_o = Q/A = 800/(4)(8) = 25$ fps
3. $F_r = V_o / [(32.2)(y_e)]^{0.5} = 25 / [(32.2)(4)]^{0.5} = 2.20$
4. $TW/y_e = 2.8/4.0 = 0.7$; $TW/y_e < 0.75$
5. Try $d_{50}/y_e = 0.45$, $d_{50} = (0.45)(4) = 1.80$ ft
 From Figure 7.24, $h_s/y_e = 1.6$
 $h_s = (4)(1.6) = 6.4$ ft
 $h_s/d_{50} = 6.4/1.8 = 3.6$ ft, $2 < h_s/d_{50} < 4$
6. From Figure 7.21:
 $L_s = (10)(6.4) = 64$ ft
 $L_{s \text{ min}} = (3)(W_o) = (3)(8) = 24$ ft, use $L_s = 64$ ft
 $L_B = (15)(6.4) = 96$ ft
 $L_{B \text{ min}} = (4)(W_o) = (4)(8) = 32$ ft, use $L_B = 96$ ft

Other basin dimensions designed in accordance with details are shown in Figure 7.21.

Use of a filter fabric or engineered blanket is recommended.

7.8.2 Design Example Number 2

Given:

8 ft by 6 ft box culvert

$Q = 800$ cfs

supercritical flow in culvert

normal flow depth = brink depth

$Y_o = 4$ ft

Tailwater depth (TW) = 4.2 ft

Downstream channel can tolerate 7 fps for design discharge

Find:

Riprap basin dimensions for these conditions.

Solution:

Note: High tailwater depth, $TW/Y_o = 1.05 > 0.75$.

- Design riprap basin using steps 1 through 6 of Design Example 1.

$$d_{50} = 1.8 \text{ ft}; \quad h_s = 6.4 \text{ ft}; \quad L_s = 64 \text{ ft}; \quad L_B = 96 \text{ ft}$$

- Design riprap for downstream channel. Use Figure 7.25 to estimate the average velocity along the channel. Compute the equivalent circular diameter, D_e , for the brink area, A , from:

$$A = \pi(D_e^2 / 4) = Y_o W_o$$

$$\pi(D_e^2 / 4) = 4(8) = 32 \text{ ft}^2$$

$$D_e = [4(4)(8/\pi)]^{0.5} = 6.4 \text{ ft}$$

$$V_o = 25 \text{ fps (Design Example Number 1)}$$

L/D_e	L (compute)	V_L/V_o (Figure 7.25)	V_L
10	64	0.59	14.7
15	96	0.36	9.0
20	128	0.30	7.5
21	135	0.28	7.0

The channel should be lined with the same size rock used for the basin. Protection must extend at least 135 feet downstream from the culvert brink.

7.8.3 Design Example Number 3

Given:

6 feet diameter cnp

$Q = 135$ cfs

$S_o = 0.004$

Mannings $n = 0.024$

Normal depth in pipe for $Q = 135$ cfs is 4.5 feet

Normal velocity is 5.9 fps

Flow is subcritical

Tailwater depth (TW) is 2.0 ft

Find:

Riprap basin dimensions for these conditions.

Solution:

1. Determine Y_o and V_o :

$$Q/D^{2.5} = 135/(6)^{2.5} = 1.53$$

$$TW/D = 2.0/6 = 0.33$$

From Figure 7.23, $Y_o/D = 0.45$

$$Y_o = (0.45)(6) = 2.7 \text{ ft}$$

$$TW/Y_o = 2.0/2.70 = 0.74, \quad TW/Y_o < 0.75$$

OK

Brink Area (A) for $Y_o/D = 0.45$ is:

$$A = (0.343)(36) = 12.3 \text{ ft}^2 \quad [0.343 \text{ is from Table 7.2}]$$

$$V_o = Q/A = 135/12.3 = 11.0 \text{ fps}$$

2. $y_e = (A/2)^{0.5} = (12.3/2)^{0.5} = 2.48 \text{ ft}$

3. $F_r = V_o / [(32.2)(y_e)]^{0.5} = 11 / [(32.2)(2.48)]^{0.5} = 1.23$

4. Try $d_{50}/y_e = 0.25$, $d_{50} = (0.25)(2.48) = 0.62 \text{ ft}$

From Figure 7.23, $h_s/y_e = 0.75$, $h_s = (0.75)(2.48) = 1.86 \text{ ft}$

$$\text{check: } h_s/d_{50} = 1.86/0.62 = 3, \quad 2 < h_s/d_{50} < 4$$

OK

5. $L_s = (10)(h_s) = (10)(1.86) = 18.6$

or

$$L_s(3)(W_o) = (3)(6) = 18 \text{ ft, Use } L_s = 18.6 \text{ ft}$$

$$L_B = (15)(h_s) = (15)(1.86) = 27.9 \text{ ft}$$

or

$$L_B = (4)(W_o) = (4)(6) = 24 \text{ ft, Use } L_B = 27.9 \text{ ft}$$

$$d_{50} = 0.62 \text{ ft, Use } d_{50} = 8 \text{ inches}$$

Other basin dimensions designed in accordance with details are shown on Figure 7.21.

Detention/Retention

8.1 Definition of Symbols

The following symbols will be used in equations throughout Chapter 8.

A	=	Drainage area, acres
C	=	Runoff coefficient, see Table 3.2 of Volume I, Hydrology
I(t)	=	Inflow to the system, cfs
O(t)	=	Outflow from the system, cfs
P	=	Rainfall depth, inches
S	=	Storage volume in the system, cfs-hrs or ft ³
t	=	Time, hours
V	=	Calculated volume, acre-feet

8.2 Introduction

Detention/retention facilities are man-made storage structures intended to mitigate the negative impacts of urbanization on storm drainage, which include:

- Increased peak flow rates.
- Loss of natural depression storage.
- Reduction of infiltration capacity in a drainage basin.
- Reduction of natural vegetation, which, in a natural state, reduces storm runoff through the process of interception.
- Increased pollutant load in surface runoff.

Detention Basin: A basin or reservoir where water is stored for regulating storm water runoff. A detention basin uses gravity-flow outlets for discharging the stored runoff.

Detention facilities do not reduce the volume of runoff, they do however lengthen the time flow will be present in the watercourse downstream of the facility. Due to the longer duration of flow downstream of detention basins, their use requires greater analysis to ensure that peak discharges are not increased downstream. Also, the impact a detention basin has on reducing the peak discharge tends to decline as the frequency of the event increases. Therefore, care must be taken not to size the outlet too large, and a range of events should be considered in the analysis.

Retention Basin: A basin or reservoir where water is stored for regulating a flood, however, it does not have gravity-flow outlets for discharging stored runoff as detention basins do. The stored water is disposed by other means such as infiltration into the soil, evaporation, injection (or dry) wells, or pumping systems.

This chapter presents the engineering methodologies and details associated with the planning, analysis and design of detention and retention facilities within Maricopa County. The guidelines herein are intended to achieve the following goals:

1. Design of detention/retention facilities that satisfy the ordinance provisions of Maricopa County and/or the individual jurisdictional agencies within the County with regard to hydraulic function and maintainability;
2. Design of detention/retention facilities that are amenities, and, where possible, incorporate multiple-use concepts; and
3. Design of facilities that will not jeopardize the quality of surface water or groundwater resources.

8.2.1 Interaction with Other Components of a Drainage System

Detention/retention facilities are components of an overall stormwater management system that is also comprised of natural and man-made channels, storm sewers, inlets, streets and other drainage structures. Their purpose is to provide temporary storage of the stormwater runoff from developed areas and to control the increased peak rates of runoff. Proper planning and design of detention/retention facilities must consider the interaction of storage with the other components of the drainage system.

The greater the number of storage facilities in a system, the more complex is the analysis of the interaction of the various discharges. Often the increased costs of construction and maintenance of a large number of smaller storage facilities offset any savings in reduced sizes of storm sewers downstream. Planning efforts should be oriented toward minimizing the number of storage facilities in a drainage basin.

As part of the planning and design process, the engineer must verify that releases from the detention/retention facility will not adversely impact downstream conditions in terms of both manner and quantity of flow. Conditions such as peak flow, velocity, flow concentration, prolongation of flow and quality of discharge are factors to be considered.

8.2.2 Limitations on Use of Detention/Retention Facilities

The requirement for a development to provide storage of runoff by detention or retention facilities will not be waived unless determined otherwise by the jurisdictional agency on a case by case basis.

In general, storage facilities are to be located so they can intercept the flow from the entire development area. If portions of the area cannot drain to a single storage facility, then additional facilities may be added to provide control of those areas as approved by the appropriate jurisdictional agency. The objective is to provide storage of runoff with a minimum number of detention/retention facilities located at optimum points within a development area. Whenever possible, the facilities shall be designed for multiple uses, such as parks or other recreational facilities, to offset the cost of open space and to encourage improved maintenance.

Residential developments shall have no single lot storage, and the design of common facilities shall not assume any individual lot on-site storage, unless approved by the jurisdictional agency. Developments with Homeowner's Associations will locate their facilities in private drainage tracts or in public sites dedicated by the developer, in accordance with the jurisdictional agency's requirements. The Homeowner's Association will maintain the private facilities, and the jurisdictional agency will usually maintain the public tracts. Common storage facilities for single family developments without a Homeowner's Association and with public streets will have maintenance provisions determined by the jurisdictional agency. The number and location of storage facilities within a development are to be approved by the jurisdictional agency. Dedication to the public may require the inclusion of recreational facilities or other features deemed necessary by the jurisdictional agency.

Single lot, non-residential developments that are not served by a public storage facility will provide the required storage on the lot itself and outside the right-of-way area.

Regional Detention/Retention Facilities: Regional detention/retention facilities are large storage facilities located at strategic sites within a drainage basin to provide control of runoff. The advantages of this type of facility are:

- The siting and design of regional storage facilities are normally incorporated as part of an overall drainage master plan. Thus, alternative siting combinations and their respective hydraulic routing effects can be investigated. Storage alternatives can be evaluated with other factors (i.e., conveyance system, land and maintenance costs), to arrive at an optimal solution for the drainage basin.

- Operation and maintenance costs are reduced. Maintenance of regional facilities is typically the responsibility of a jurisdictional agency. The reduced cost of operation and maintenance can often offset the increased cost of tributary storm sewers which must be sized to carry higher peak rates of flow.
- Regional facilities are more effective and reliable because they are planned, designed and maintained as part of a total drainage system. On-site facilities can be less reliable and less effective because they are constructed randomly as a basin develops and because maintenance efforts can vary. The result of on-site facilities is a higher percentage of malfunctions.

Advance planning is the key element in the regional approach to stormwater detention/retention. The jurisdictional agencies within Maricopa County have agreed that basin-wide master drainage planning is necessary for the development of cost-effective systems for stormwater management. Planning for regional detention/retention facilities for a drainage basin typically includes:

1. Development of an optimum drainage master plan for the basin in order to achieve an efficient and cost-effective drainage systems, and to ensure that multiple use opportunities are preserved.
2. Multi-jurisdictional cooperation, because natural drainage basins do not necessarily follow jurisdictional boundaries.
3. Participation by property owners, developers, engineers and the general public.
4. A plan for implementation that incorporates construction phasing of facilities.
5. Establishing a framework for fair and equitable financing of capital and maintenance costs.

8.3 Design Criteria

This section presents certain guidelines, procedures and criteria to be used in the analysis and design of detention and retention facilities. Because specific policies and criteria vary, the designer must contact the jurisdictional agency for the area in which the basin will be located before beginning design.

8.3.1 Criteria for Detention/Retention Facilities

The following general criteria apply to the design of stormwater detention/retention facilities.

8.3.1.1 Design Frequency:

All detention/retention facilities incorporated within new developments will be designed to retain the peak flow and volume of runoff from the 100-year, 2-hour duration storm event. In the special case of when a detention only facility is allowed, the requirement to retain the 100-year 2-hour runoff volume may be waived. However, the peak discharge requirement must still be met, and the effects of using a detention only facility on more frequent events must be determined.

In jurisdictions where multi-frequency control is required, the design will be prepared to regulate the peak discharge rates for one or more storm events in addition to the 100-year storm. Specific multi-frequency events shall be verified with the appropriate jurisdiction.

8.3.1.2 Hydrology: Procedures and criteria for development of inflow hydrographs for detention/retention facilities are described in the *Drainage Design Manual for Maricopa County, Volume I, Hydrology*. Some jurisdictional agencies have developed simplified equations for determining the volume required for retention. The engineer should verify the methodology for calculation of the required storage volume with the appropriate jurisdiction.

Volume Calculations: Volume calculation should be done by applying the following equation:

$$V = C \left(\frac{P}{12} \right) A \quad (8.1)$$

In the case of volume calculations for detention/retention design, P equals the 100-year, 2-hour depth in inches, from Figure 8.1. The amount of rainfall for other frequencies and durations can be determined by using Section 2.2 of Volume I, Hydrology.

Off-site flows may not be routed through a retention facility unless specifically approved by the appropriate jurisdictional agency.

For a typical stormwater detention facility, there are three variables to be considered in flood routing through the structure:

1. Inflow to the facility, which varies as a function of time;
2. Outflow from the facility, which varies as a function of time; and
3. Storage, which is the result of the difference between the inflow and outflow for a period of time or time interval.

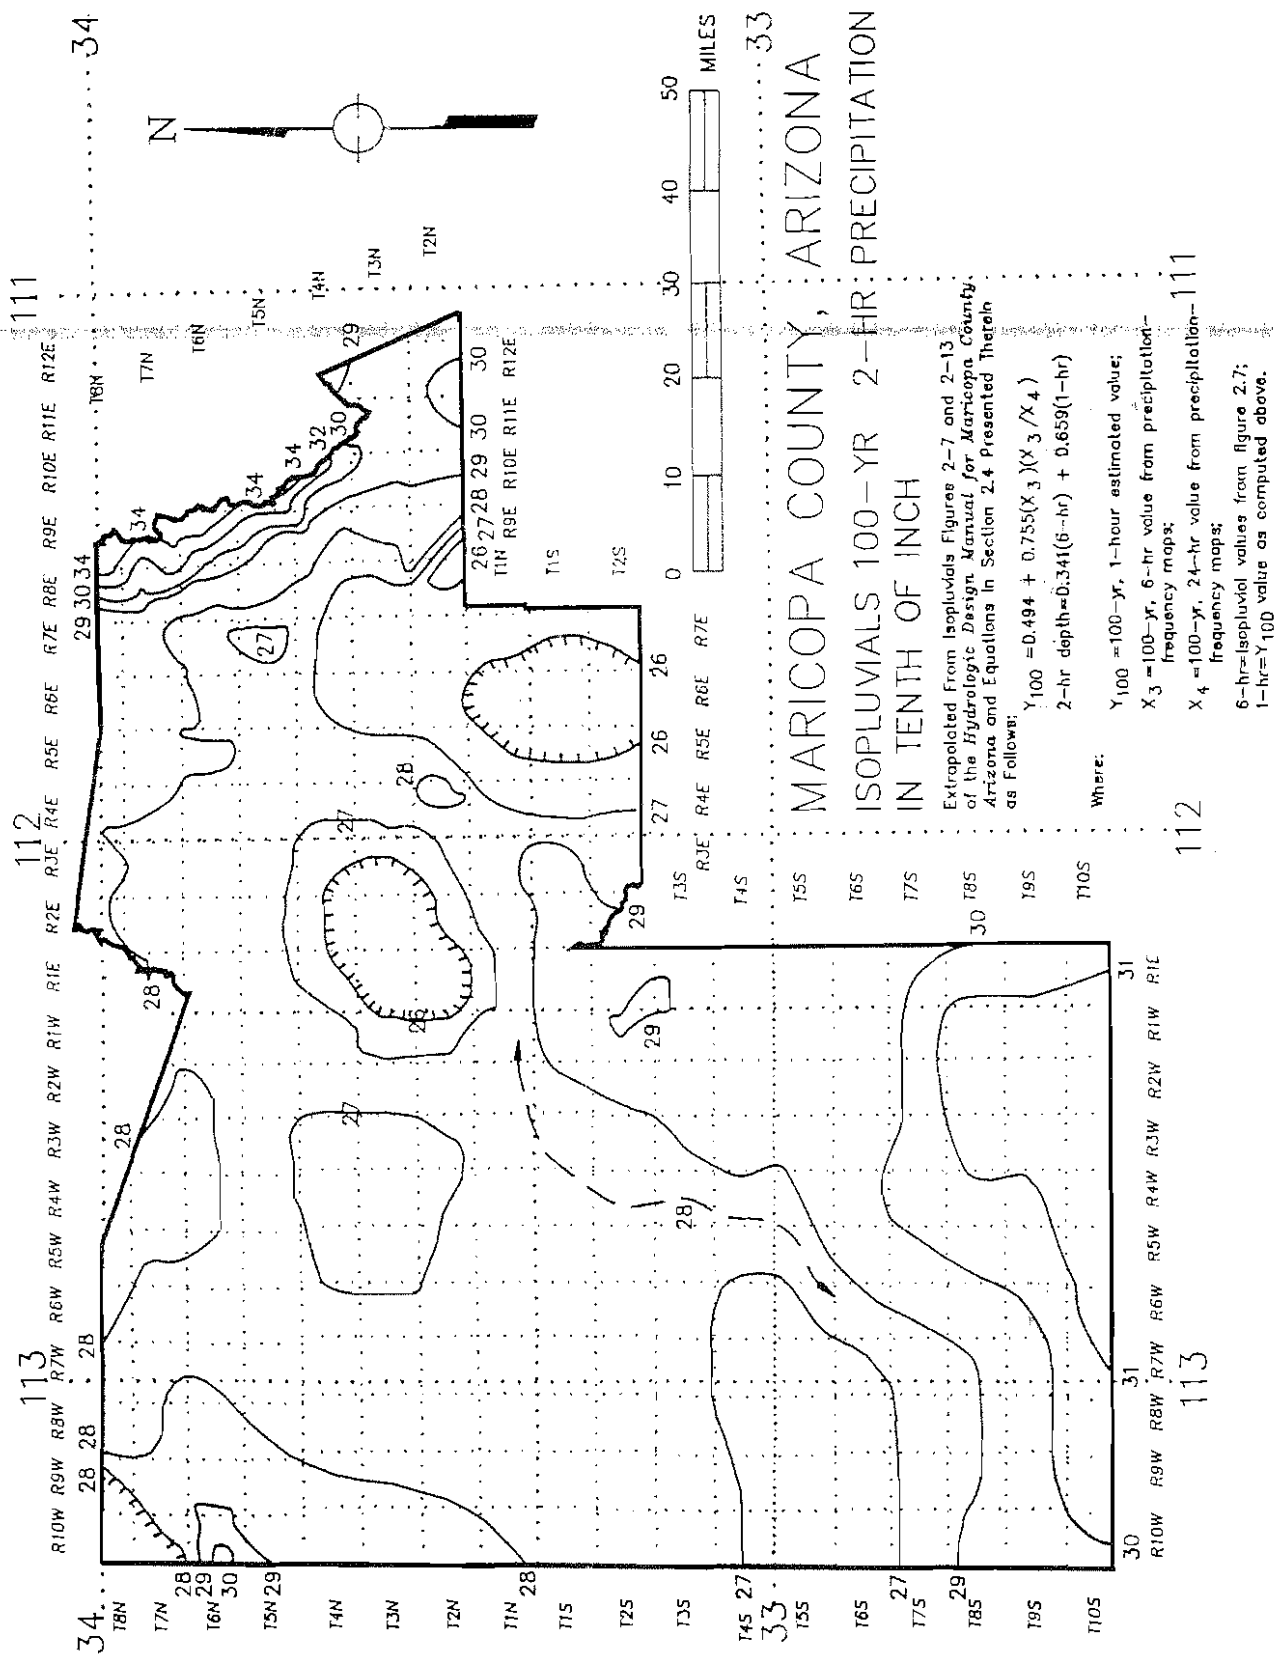

Figure 8.1
Isopluvial 100-Year, 2-Hour Precipitation

Figure 8.2
Flood Routing (Inflow and Outflow Hydrograph)

Figure 8.2 illustrates the general relationship among the three variables that must be considered for flood routing through a structure.

The outflow hydrograph from a proposed stormwater detention facility shall be determined using the "Storage Indication" or "Modified Puls" method of flood routing. See Section 8.8 for a detailed description of this routing procedure. Other similar hydrologic routing methods may also be used, provided that the chosen method is first approved by the appropriate review agency. If a computer program for flood/reservoir routing is intended to be used, documentation of the program shall be submitted to the appropriate review agency prior to commencing design. Non-tributary flows may not be routed through a detention facility unless specifically approved by the jurisdictional agency.

Detention ponds in series (i.e., when the discharge of one facility becomes the inflow of another) are complex and require special consideration and design by a hydraulic engineer. If such a system is unavoidable, the engineer must submit a hydrologic analysis which demonstrates the system's adequacy. This analysis must incorporate the construction of hydrographs for all inflow and outflow components.

8.3.1.3 Sedimentation in Detention/Retention Basins: Depending on the watershed, sediment deposition into detention/retention basins may be significant enough to reduce storage volume. Therefore, it is important during the design process to estimate the sediment yield from the watershed and add this volume to the storage volume. This can

be accomplished by various empirical methods listed in the references below and/or by using the HEC-6 sediment routing computer model.

- a) PSIAC (Pacific Southwest InterAgency Committee) Method. This procedure, developed for planning level analysis in the Southwestern United States, uses generalized watershed characteristics to estimate watershed soil loss rates. This method is explained in Appendix A of the Arizona Department of Water Resources, *DESIGN MANUAL FOR ENGINEERING ANALYSIS OF FLUVIAL SYSTEMS*, 1985. The original source is the State of California, Department of Conservation, *EROSION AND SEDIMENT CONTROL HANDBOOK*, 1978.
- b) MUSLE (Modified Universal Soil Loss Equation) Method is an empirically derived method using the major parameters of the Universal Soil Loss Equation to estimate sediment yield on a per storm basis. This method was developed by Williams (1975) and can also be found in Appendix B of Arizona Department of Water Resources, *DESIGN MANUAL FOR ENGINEERING ANALYSIS OF FLUVIAL SYSTEM*, 1985.
- c) U.S. BUREAU OF RECLAMATION Method provides empirical relationships between sediment yield and other watershed parameters such as drainage area, discharge and reservoir depth. These methods are described in Appendix A of U.S. Department of Interior, Bureau of Reclamation, *DESIGN OF SMALL DAMS*, 1987.
- d) NATIONAL COOPERATIVE HIGHWAY RESEARCH PROGRAM SYNTHESES No. 70 Method provides a sediment yield relationship involving parameters such as watershed slope, soil erodibility (related to SCS Curve Number for soil groups), drainage area and erosion control factor. This research was sponsored by AASHTO and can be found in Transportation Research Board, Synthesis No. 70, *DESIGN OF SEDIMENTATION BASINS*, June 1980.

These methods or any other approved methods can be used to estimate sediment deposition in the detention basin. A HEC-6 sediment transport model may be used if enough information exists for this to be accomplished. This is an elaborate method that routes sediment through the channel into the basin and may only be necessary for large projects. To obtain the required sediment storage volume the annual sediment deposition, in acre feet per year, must be determined and multiplied by the expected number of years between sediment removal. It may also be necessary to install sediment gauges throughout the basin for monitoring rate of sediment deposition.

If sediment yield has been determined to be excessive or there is a great potential for debris deposition (such as in the case of alluvial fans), then a sediment basin would be required upstream of the detention/retention basin.

8.3.1.4 Siting and Geometry: With respect to siting, detention/retention facilities which utilize a method of subsurface disposal shall be located such that the infiltration surface will be a specific distance, both horizontal and vertical, from any functioning water well.

The appropriate jurisdictional agency should be contacted regarding regulations governing the siting of such facilities near wells or near the static groundwater table.

Basic requirements regarding facility shape, side slopes, depth and bottom configuration are provided below. Additional details are presented in Sections 8.4, 8.5, and 8.6 in conjunction with guidelines regarding safety, operation and maintenance, aesthetics, and multiple use considerations.

Shape: As a general rule, curvilinear, irregularly shaped facilities will have the most natural character. A wide range of shapes can be considered and utilized to integrate the detention facility with the surrounding site development. Smooth curves should be used in the plan layout of the grading for the facility.

Side Slopes: Where grass is intended to be established, side slopes shall not be steeper than 4 horizontal to 1 vertical. Where other protection measures are intended, such as shrub planting, rock riprap or other structural measures, slopes shall not exceed 3 horizontal to 1 vertical unless approved by the appropriate jurisdictional agency. Where slopes abut the street right-of-way, the minimum slope shall be 4 horizontal to 1 vertical regardless of surface treatment. Some jurisdictions may require a flatter slope. The designer should verify the slope requirement prior to commencing design.

Transitions from slopes to level ground at the top and bottom of a facility shall be smooth curves. In all cases, slopes must be designed to allow for safe operation of maintenance equipment. Refer to Section 8.5.1 for provision of maintenance access. Side slope design should be done with the visual character of the completed facility in mind. A more natural appearance can be achieved by varying side slopes within a detention area.

Depth and Bottom Configuration: Maximum ponding depth and freeboard requirements vary within Maricopa County and specific criteria for such must be verified by the designer with the appropriate jurisdictional agency. With respect to grading, deep facilities should be avoided, if possible. For facilities with a depth in excess of three feet, consideration should be given to the use of flatter side slopes or the provision of intermediate benches along side slopes. The bottom shall be designed to drain to a low flow channel for a detention facility.

8.3.1.5 Drain Time:

The design of all detention/retention facilities shall be such that the stored runoff is completely discharged from the facility within 36 hours after the runoff event has ended.

8.3.1.6 Lining/Surface Treatment: In keeping with the goal of detention/retention facilities as amenities that incorporate multiple use concepts where possible, grass and/or landscape plantings are preferred surface treatments. As a general rule, grass and plant species used for landscape development and revegetation should be native to Maricopa County. A registered landscape architect should prepare the landscape design with consideration toward use of plant species appropriate for the level and frequency of inundation of the facility. Permanent irrigation systems are required for grass areas and most types of basin revegetation and landscaping. However, use of native and drought-tolerant species (including seeding) may only require a temporary system to obtain effective germination and establishment. Whether permanent or temporary, that portion of the irrigation system within the flood zone must be designed to tolerate inundation and silt accumulations.

The use of inert materials is appropriate for stabilization and erosion control where steep slopes are unavoidable, along channels, at inflow points, at the outlet control structure and any other location where flowing water may threaten stability. Use of these materials should be properly engineered and should respond to aesthetic considerations. Inert materials for erosion control include:

- Loose rock riprap with a specific, engineered gradation
- Loose or grouted boulders (minimum dimension 18 inches and larger)
- River stone
- Gabions
- Soil cement and concrete

Designs that combine landscape planting with the use of inert materials are recommended. Voids can be designed within the inert material to allow installation of plants. The result is a durable and attractive method of protection.

8.3.1.7 Low Flow Channels: A low flow channel is required in the bottom of a detention facility to provide positive routing of drainage to the primary outlet structure. An example of a rectangular concrete low flow channel is provided in Figure 8.3. The engineer will provide design of the reinforcement of the channel. The channel shall have a 0.5 percent maximum longitudinal slope. Alternative low flow channel designs may be considered at the discretion of the individual jurisdictional agency, however, use of loose rock or other movable materials can only be made after careful consideration.

8.3.1.8 Detention/Retention Facility Inlet and Outlet Structures: Conveyance of runoff into a retention facility often involves directing the inflow down a slope into the storage area. The design of an inlet structure shall be such that inflow is directed into the facility in a non-erosive manner and without adverse impacts to the retention facility or to upstream areas. The designer is referred to analysis methods presented in Chapter 6 for the design of inlet structures.

Retention facilities shall be drained by either a positive gravity outlet, a pump station, or by subsurface disposal measures.

Figure 8.3
Rectangular Concrete Channel Section
 (Adapted from: WRC Engineering, Inc., 1985)

Outlet structures are an important component of stormwater detention facilities since they control the rates of release from the facility, the water depth, and storage volume in the facility. Outlet structures are classified as: 1) primary outlet structures that provide the hydraulic control for the specific design event(s) required by the jurisdictional agency; and 2) emergency spillways that provide safe routes, typically via surface overflow, for storm events in excess of the design frequency or in the case of debris blockage or malfunction of the primary outlet structure.

Primary Outlet Structures: Within Maricopa County, jurisdictional agencies may require attenuation of a single frequency storm or a number of frequencies. Refer to the specific requirements of the jurisdiction where the design is being prepared; however, two-stage and multi-stage control structures are becoming more widely used. Figure 8.4 presents examples of single frequency and multi-frequency outlet control structures.

The minimum allowable pipe size for primary outlet structures is 12-inches in diameter.

If the flow capacity of an outlet pipe must be further reduced, an orifice plate may be attached, as shown on Figure 8.5(a). The orifice plate must be constructed of heavy, galvanized steel and attached by tamper-proof bolts. Other outlet configurations may be allowed provided they meet the requirements of the permitted release rates at the required volume and include proper provisions for maintenance and reliability.

Primary outlet structures, particularly those controlling multiple storm events, are often special design structures unique to specific site applications. Consideration must be given to structural adequacy and flotation under hydrostatic loads.

Trash Racks: Trash racks shall be provided for pipe and orifice outlets.

The trash rack assembly shall be hinged or removable to allow access to the outlet construction. The mesh or bar screen shall be fabricated of steel designed to withstand the hydrostatic load resulting from the 100-year design ponding with screen openings blocked. The rack assembly shall be galvanized steel or steel with a protective coating suitable for exposure to sunlight, as well as submerged conditions. Figure 8.5(b) provides guidelines for determining the open area requirements for trash racks. An anti-vortex device should be included with the trash rack design if vortices are anticipated which could affect hydraulic efficiency and cause erosion of adjacent earth slopes.

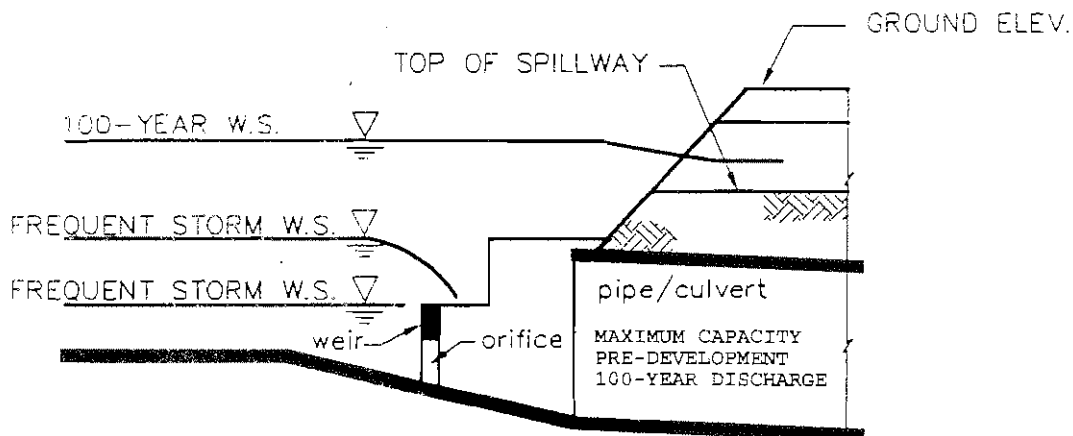

Energy Dissipation at Outlet: Adequate energy dissipation measures shall be provided at the downstream end of primary outlet structures. Such measures shall be designed to control local scour at the pipe outlet and to reduce velocities to pre-development conditions prior to exiting onto the downstream property.

NOTE: For orifice diameter less than 3", use a minimum clear opening of 2 ft^2 .

Figure 8.5
Detention Facility Outlet Detail
 (Adapted from: WRC Engineering, 1987)

Emergency Spillways: Emergency spillways are normally surface overflow weirs, channels, or combinations thereof, provided for the safe overflow and routing of floodwaters under unusual circumstances. Such situations include the blockage or malfunction of the primary outlet structure or the occurrence of a storm event larger than that for which the facility was designed. Consideration must be given to the layout and configuration of the emergency spillway so that excess flow is routed in the same manner and direction as would have occurred under pre-development or historic conditions. Emergency spillways must be designed to convey the unattenuated 100-year peak discharge at non-erosive velocities. For criteria regarding design of emergency spillways for embankments, refer to Section 8.3.3.4.

8.3.1.9 Subsurface Disposal: The primary methods of underground disposal of stormwater runoff at retention facilities are engineered basin floors and dry wells. Infiltration rates of basin floors or dry wells shall not be used in determining outflow rates in flood-routing procedures.

Engineered Basin Floors: Analysis and design of the bottom of a retention facility intended for subsurface disposal is detailed in *Underground Disposal of Stormwater Runoff Design Guidelines Manual* (USDOT, FHWA, 1980); refer to this publication for specific design criteria.

Dry Wells: Dry wells may be used for subsurface disposal of stormwater, if approved by the jurisdictional agency, and if criteria such as subsurface strata permeability, groundwater levels and maintenance can be satisfactorily addressed. The main cause of dry well failure is clogging of the transmission media (gravel) by silt and debris. Failure can be hastened by poor maintenance. Figure 8.6 shows a typical dry well installation, while Figure 8.7 shows examples of surface treatments.

All dry wells must be registered with the Arizona Department of Environmental Quality.

The following list of general requirements and criteria shall be used in the design and construction of dry wells (or other methods of subsurface disposal of stormwater). In addition, the engineer is referred to specific dry well policies of the applicable jurisdictional agency within Maricopa County.

- The feasibility of subsurface disposal of stormwater at a site must be documented by field investigations and a report by a registered civil engineer. Field investigations shall include percolation tests to obtain permeability rates for use in the design of the retention facility. The accepted design disposal rate for a dry well is not to exceed 0.1 cfs per well unless a greater rate can be supported by a detailed, certified soils report. Should the soils report indicate a higher rate, a conservative value of 50 percent of the higher rate (not to exceed 0.5 cfs per well) shall be used to compensate for deterioration over time. The infiltration surface of the subsurface disposal facility must be located a specified minimum distance from the static groundwater table, both horizontally and

vertically, depending on the type of development proposed. The appropriate jurisdictional agency should be contacted for specific criteria regarding this item.

- The design of a dry well must include provisions for trapping sediment within a settling chamber. This measure will significantly increase both the efficiency and useful life of the well. Once a year, at a minimum, the settling chamber should be inspected, and it should also be inspected after any major inflow to the dry well. Sediment shall be removed from the chamber at such a time that approximately one-half of its capacity is filled. This level of sediment buildup shall be clearly marked on the inside of the settling chamber. All sediment removed from a settling chamber shall be disposed of either at an authorized sanitary landfill or at any other suitable location approved by the governing jurisdiction.
- A test well shall be installed for any retention facility utilizing dry wells for stormwater disposal. Upon approval of performance, this test well may then be used as one of the functioning dry wells within the retention facility. For purposes of design, the "initial" well-injection rates (determined from the test well) shall be multiplied by the factor 0.5 in order to establish "aged" well-injection rates to be used for purposes of determining the required number of dry wells ultimately needed within the facility.
- Infiltration rates of dry wells shall not be used in determining outflow rates in flood-routing procedures. Any retention facility which relies solely upon infiltration as its method of drainage shall be sized to contain the maximum storage volume that would be required without considering an outflow rate.
- Disposal methods using infiltration shall not be permitted for stormwater runoff which carries significant concentrations of sediment. This includes stormwater runoff flowing through sand bed channels, as well as stormwater runoff emanating from a predominantly natural watershed.
- During site development, all dry wells shall be securely covered with filter cloth or other material to prevent the introduction of excessive sediment into the settling chamber.
- Retention of runoff emanating from industrial developments and infiltration of runoff to the subsurface will be handled on a case-by-case basis by the appropriate reviewing agency.
- Runoff stored in a retention facility shall be completely drained from the facility within a maximum time period of 36 hours after the runoff event has ended. Dry wells that cease to drain a facility within the 36-hour period shall be replaced by the owner with new ones, unless an alternate method of drainage is available.

Figure 8.6
Typical Dry Well Installation
 (McGuckin Drilling Inc., 1987)

- A. Add a concrete pad for heavy traffic areas.

- B. For landscaped retention ponds and planters. No paving or pad. In areas where silt might flow to drywell, use C.

- C. Use in landscaped retention/detention basins or where heavy silt flow is anticipated. Height should be 4" ±.

- D. A special design where unstable soil conditions could cause surface subsidence. Also installed with connecting pipes and trenches.

Figure 8.7
Typical Dry Well Surface Treatments
(McGuckin Drilling Inc., 1987)

8.3.1.10 Permanent Pools: Certain jurisdictions within Maricopa County permit the design of a detention facility that incorporates a permanent pool for aesthetic purposes. The engineer should contact the appropriate jurisdiction for specific criteria and regulations regarding such facilities. General considerations for facilities incorporating permanent pools are listed below:

- Flood storage volume shall be maintained above the level of the permanent pool. Provision for draining the full depth of the pond shall be included at the outlet structure.
 - Maintenance of a minimum water level should be ensured by the inflow from the watershed and/or by augmentation from other sources during prolonged dry periods and by the capability of the bottom of the facility to retain water. Seepage and evaporation losses should also be considered.
 - Maintain water quality and minimize algae growth by designing for sufficient minimum depth and incorporating use of recirculation and aeration measures.
 - Consider public safety as primary in the design of all features related to the permanent pool.
 - Geometric characteristics of the pond include:
 - Choose bottom lining material suitable for retention of water and with consideration toward maintenance (i.e., ease of sediment removal, etc.). Provisions for completely draining the pond should be made.
 - Create aesthetic yet maintainable edges. Edge design also should consider the effect of drawdown of the water surface. That is, a drop in water surface elevation should not create a wide expanse of unsightly shoreline. Similarly, the area surrounding the permanent pool should be designed for periodic inundation. The area should drain completely and return to a stable surface following a flood event.
 - Provision of stable side slopes above and below the permanent water surface.
- The pond edge shall be designed to minimize safety hazards. Water depth should be limited to 1.5 to 2 feet within 8 feet of the shoreline.
- Resolve permanent pool water depth issues versus safety needs; a 3-foot depth at shoreline required to limit pond edge vegetation growth exceeds the recommended pond edge depth (1.5 to 2.0 feet). Therefore, other safety measures must be considered (see Section 8.4).

- The design should consider measures to minimize sediment inflow to the pond. Once sediment has entered the permanent pond, then removal can be expensive and may require draining the pond. Erosion should ideally be controlled at the source or by mitigation measures along the incoming channel. However, if such measures are not feasible, a sediment trap should be designed at the pond inflow location to intercept the majority of the incoming sediment and to facilitate removal (see Section 8.7.4).
- If the detention facility and permanent pool are created by a retaining structure, such as an earth embankment, then the design guidelines for the embankments shall be followed, with particular emphasis on seepage control and embankment stability (see Section 8.3.3).
- Potential impacts downstream shall be considered. The designer should be aware that an impoundment may improve, worsen or maintain existing downstream flow characteristics, and that any changes, even apparent improvements, may be viewed as infringements of downstream riparian rights.
- Since a permanent pool is most often desired for creation of a focal amenity for a development, it is appropriate that a registered landscape architect work in conjunction with the engineer to achieve an aesthetic design with consideration of costs of construction and maintenance.

8.3.2 Criteria for Special Detention/Retention Methods

Special methods for stormwater detention/retention include underground storage, conveyance storage, roadway embankment storage, and storage in parking lots, pedestrian plazas, courtyards and common areas.

The use of rooftops as storage areas for runoff is not permitted in Maricopa County.

Application of the special measures discussed below is regulated according to specific jurisdictions within Maricopa County. Contact the local jurisdiction before beginning to design using any of these methods.

Since the following methods often result in facilities near buildings, it should be emphasized that the finished floor elevation of a structure shall be a minimum of one foot above the 100-year water surface of the detention/retention facility. The finish floor elevation needs also to be above the emergency outfall of the basin.

8.3.2.1 Underground Storage: This type of storage involves the construction of underground tanks, pipes, or vaults which accept stormwater runoff by means of inlets and storm drain pipes. Due to the high cost of this type of installation, it is generally

limited to high-density developments, where surface storage is not feasible due either to the scarcity or high cost of land—or both.

Underground storage facilities must be provided with some method of drainage (i.e. gravity drains, pumps, or infiltration). In all cases, manholes (or some other means of access to the underground storage facilities) must be provided for maintenance purposes.

8.3.2.2 Conveyance Storage: During the period that channels and floodplains are filling with runoff, the stormwater is being stored in transient form. This type of storage is known as conveyance storage. Construction of slow velocity channels with large cross sectional areas assists in the accomplishment of such storage. Conveyance storage systems are usually feasible only on large projects, and require detailed dynamic modeling for analysis.

8.3.2.3 Roadway Embankment Storage: When feasible, use of roadway fill slopes as an embankment for a detention basin provides an economical means of stormwater storage. Special considerations must be given both to the stability of the embankment and to the protection of the embankment from erosion. Additionally, State of Arizona dam safety requirements may need to be addressed if the embankment height and/or the potential storage volume exceeds certain limits (see Section 8.3.3.1).

8.3.2.4 Parking Lot Storage: Using parking lots for detention/retention is a special case of surface storage. It is an economical option for meeting detention/retention requirements in high density commercial and industrial developments. Planning of areas within a parking lot which will accept ponding should be such that pedestrians are inconvenienced as little as possible.

Refer to local jurisdictional standards on the percentage of the parking lot to be used as retention area and the allowable ponded depth. The maximum depth of ponded water within any parking lot location shall be one foot (1 ft). Deeper ponding should be confined to remote areas of parking lots, whenever possible.

Drainage of parking lots can be accomplished by means of dry wells (if permitted), curb openings, weirs, storm drains, orifices in walls, or gated outlets.

The minimum longitudinal slope permitted within parking lot storage facilities is 0.005 ft/ft, unless concrete valley gutters are provided. With concrete valley gutters, a minimum longitudinal slope of 0.002 ft/ft may be permitted.

8.3.2.5 Storage in Plazas, Courtyards and Common Areas: Landscaped common areas, pedestrian plazas and courtyards, which are typically provided in conjunction with high density residential, commercial and office developments, provide opportunities for multiple use as stormwater detention/retention facilities. Such facilities should be designed to minimize public inconvenience, especially during frequent storm events. Public safety issues are also very important with this type of facility (see Section 8.4).

Positive drainage to the outlet structures and trash/debris control must be provided to assure that the facility drains completely and efficiently.

8.3.3 Embankment Design Criteria

Whenever possible, detention/retention facilities should be constructed with the storage volume located entirely below the natural ground surface adjacent to the basin. However, in some instances this may not be possible, and embankments may be necessary to provide the required storage volume. Since the use of embankments may create a potential downstream flood hazard due to failure of the embankment, the following design considerations must be addressed in conjunction with their use. For additional information and guidelines for the design of embankments for detention/retention facilities, refer to *Design of Small Dams* (USBR, 1987).

8.3.3.1 State Dam Safety Requirements: The Arizona Department of Water Resources (ADWR), Division of Safety of Dams, has legal jurisdiction over all dams (embankments) which exceed certain height and storage limits. ADWR defines a jurisdictional dam as “either 25 feet or more in height or stores more than 50 acre-feet. If it is less than six feet in height regardless of storage capacity or does not store more than 15 acre-feet regardless of height, it is not in jurisdiction.”

Figure 8.8 illustrates the difference between a jurisdictional and a non-jurisdictional dam. ADWR should be contacted regarding specific dam-safety requirements in conjunction with the design of any embankment which might come under their jurisdiction. Those which do fall within the jurisdiction of ADWR shall comply with their applicable design requirements.

8.3.3.2 Non-jurisdictional Dam Design: Embankments for detention/retention facilities in Maricopa County that are “non-jurisdictional” according to the state criteria will generally be classified by the state as small dams with an associated hazard potential. The hazard potential classification is related to the conditions downstream of the dam. In the urban environment of Maricopa County, the potential for probable loss of life and excessive damage to development downstream (existing or future) is great. Therefore, all dams for detention/retention facilities will be considered as having high hazard potential.

The design reports, calculations, plans and specifications for construction of an embankment for a detention or retention facility shall be prepared by, or under the direction of, a professional engineer registered under the laws of Arizona, and having proficiency in civil engineering as related to dam technology. The engineer should check with the appropriate jurisdiction for specific submittal requirements for embankment dam designs. Figure 8.9 shows a typical section of an embankment dam with common components applicable to a typical detention or retention facility.

A JURISDICTIONAL DAM is either 25 or more feet in height or has capacity to store more than 50 acre-feet.

If a dam is less than six feet in height, regardless of storage capacity, it is not jurisdictional.

If a dam has 15 acre-feet or less of storage capacity, regardless of height, it is not jurisdictional.

HEIGHT is the vertical distance from the lowest point on the downstream toe (at natural ground) to the spillway crest.

CAPACITY is the maximum storage that can be impounded when there is no discharge of water.

State of Arizona Jurisdictional Dam Definition
 (Adapted from: State of Arizona Department of Water Resources, Safety of Dams Section)

Figure 8.9
Typical Section of a Detention/Retention Facility Embankment Dam

8.3.3.3 Geotechnical Engineering Studies: A geotechnical engineering study shall be conducted prior to the design of any dam. The study shall provide information on the dam site conditions such as the dam foundation and abutments (valley floor and sides), and shall provide evaluation of soil materials proposed for construction of the dam. Samples obtained from borings and exploratory pits can be tested under laboratory conditions to evaluate more precisely the soil and rock classification properties, strength, permeability, compatibility and other specialized tests pertinent to the specific project conditions. Analyses shall be conducted to evaluate conditions such as embankment slope, foundation stability, embankment and foundation seepage, internal and external erosion potential and embankment settlement. The results of these analyses are used to develop criteria for economic and safe design and construction of embankment dams. These criteria include the types and zones of embankment fill materials based on using available borrow materials, upstream and downstream embankment slopes, and recommended measures for control of seepage.

8.3.3.4 Emergency Spillway: All embankment dams for detention/retention facilities shall incorporate an emergency overflow spillway for the safe overflow and routing of floodwaters under unusual circumstances. Such conditions include the blockage or malfunction of the primary outlet structure or the occurrence of a storm event larger than that for which the facility was designed. Floodwaters that might otherwise overtop the embankment shall exit the facility via the emergency spillway and flow downstream in the same manner and direction as would have occurred under pre-development or historic conditions.

The design of emergency spillways shall incorporate adequate erosion control and energy dissipating measures to insure the stability of the embankment. Due to the high hazard potential of embankment facilities in Maricopa County, the minimum design standard for emergency spillways shall be as indicated in Table 8.1. Total freeboard and residual freeboard dimensions shall conform to the applicable ADWR design requirements.

Table 8.1
Emergency Spillway Design Capacity Requirements for an
Embankment Dam that is not Regulated by ADWR

Dam Height	Spillway Design Capacity
$H \leq 6 \text{ ft.}$	Unattended 100-year inflow
$6 \text{ ft.} < H < 25 \text{ ft.}$	$\frac{1}{2}$ Probable Maximum Flood

8.3.3.5 Primary Outlet Structure: The primary outlet structure is the main outlet structure by which stormwater is discharged from a detention/retention facility. It is typically a closed conduit structure with an inlet specifically designed to control a single frequency storm or multiple events depending on the requirements of the specific jurisdiction. Examples of typical primary outlet structures and discussions of related components such as trash racks and energy dissipation structures are presented in Section 8.3.1.8 (Figures 8.4 and 8.5). Special consideration must be given to seepage control along outlet conduits within an embankment dam, as discussed below.

8.3.3.6 Seepage: There are basically two categories of seepage considerations in embankment dam design. The primary concern is that seepage does not adversely affect the integrity or stability of the dam. The other category, water storage loss, is something the owner is usually most concerned about. This category relates to design of additional seepage control measures as required to maintain a permanent pool for reuse (water harvesting), or aesthetic or recreational purposes. Analyses shall be conducted in the following areas at a minimum, to address control of seepage for the primary function of detention or retention of stormwater.

Foundation: The flow of water through a pervious foundation produces seepage forces as a result of the friction between the percolating water and the soil medium. As the water percolates upward at the toe of the embankment, the seepage forces lift the soil by reducing its effective weight. In certain cases, this “piping” of the foundation soil can result in the failure of an embankment. A very common approach used is to excavate a cutoff trench into the foundation strata, typically into an impervious layer. The trench is then carefully backfilled with relatively impervious material.

Embankment: Seepage through an embankment will occur, even with the tightest materials. On the upstream side of the dam, the embankment soils will reflect a water level equal to the impounded water level. As the water seeps through the dam, its pressure reduces and the water level drops. Design of the embankment should be such that seepage at the downstream toe occurs with no residual pressure. If the seepage were excessive, or were to emerge at an unplanned higher location, then erosion could begin at the discharge point and rapidly remove materials from within the embankment. Toe drains are typically designed to intercept the planned seepage flow, preventing nuisance conditions and enhancing slope stability.

Slope Stability: Combined with seepage analysis, slope stability analysis is critical. The forces pushing a mass of soil are analyzed with respect to the force resisting that movement. A related problem is slope stability during conditions of rapid change. A common concern is during a rapid drawdown, such as when operational problems with outlet works or seepage occur. With such operational problems, pressures in the soil may cause the slopes to fail during drawdown.

Piping along Boundary Conditions: Wherever there are boundary conditions, such as along an outlet conduit, spillway wall, cutoff trench or more subtle situations (such as layers of fill that have been rolled to a smooth hard surface), there is the potential of creating a more direct route for piping. The water flows at a higher erosive rate because it has a shorter, more efficient route. The technique that is often used along conduits and walls is to construct cutoff collars which extend laterally at intervals into the trench or embankment. When a much longer flow path is created, piping is minimized.

8.4 Safety

Public access and safety are inherent elements in the design of a detention or retention facility. These elements are of primary importance, particularly in the case of multiple-use facilities where public use is encouraged in areas subject to potential flooding.

Safety at detention/retention facilities is addressed in two ways. The first relates to the need to identify and communicate potential hazards to the public. For example, with proper signage, users can be made aware of the existence of potential hazards, such as flooding, high velocity flows, etc.

The second relates to the design and maintenance of the facility. Appropriate steps must be taken to mitigate potentially dangerous conditions. Where the dangerous condition cannot be prevented, appropriate measures must be implemented to keep users away from hazardous locations. If these safety concerns are appropriately addressed, there is no reason why public use of detention/retention basins should not be allowed and encouraged.

8.4.1 Identification of Potential Flood Hazard

Signs will be the principal means by which users of the facility are advised of potential flood hazards.

Signs should be provided at all designated entryways of detention/retention facilities. They should also be provided at intervals (approximately 100 feet) around the perimeter of the facility to inform visitors who might gain access at other than designated entrances.

In addition to entry and perimeter signs, signs should be installed within the facility. These signs should restate the potential flood hazard and should provide directions for appropriate routes out of the basin area should flooding occur.

Signs should indicate that rain in the immediate area is not a prerequisite for high water levels. They should indicate that storms elsewhere in the watershed can result in flooding, and in some cases, a wall of water may enter the facility. An interpretive display sign illustrating this phenomena may be appropriate at each major entrance.

To be effective in communicating the potential flood hazard to the public, signs must be in place when and where needed. Consideration must be given to durability and vandal-resistance. Materials, fasteners, installation techniques, mounting heights, etc. must be evaluated in the design of important warning signs.

In some instances, warning devices other than signs may be appropriate and necessary. An audible alarm or a system of flashing lights, with a remote sensor activated by floodwater in an upstream channel, might be considered. This might be necessary in locations where watershed and inlet characteristics could result in rapid filling of the facility.

Where parking lots are designed such that floodwaters will inundate the area, signs should be posted to alert users. Overnight or long-term parking should be prohibited.

8.4.2 Inlet Structures

Often higher flood flow is directed into a multiple-use facility by an overflow side channel spillway or by a drop structure. A large volume of water entering the facility at high velocity can literally wash away an individual who is on or near the inlet structure. The design of an inlet that minimizes the velocity of incoming water will greatly enhance safety and should be included in the criteria for inlet structure design. Railing or fencing shall be designed at the top of all structural walls.

It is also important to design inlet structures so that they do not become attractive nuisances. They should not be suitable for potentially dangerous activities such as skateboarding and motor-cross biking. In this regard, a rough textured surface might be more appropriate than a smooth, troweled-finish concrete surface. Features that preclude inappropriate uses of inlet structures should be used.

As noted above, signs located around the inlet structure can inform the public of potential hazards associated with the area. Informative and well-maintained signs will be critically important in basin inlet areas.

8.4.3 Outlet Structures and Spillways

There are two elements of the safety issue as related to outlet structures and spillways. The first deals with the safety of the user during flood conditions. The second deals with the uninterrupted operation of the outlet or drain required for the release of impounded water.

User safety must be of primary concern with the design of outlets or drains. They must be designed so that it is not possible for a user to be washed into an outlet pipeline and trapped. This is particularly important when considering children using the outlet structures as a playground.

A properly designed trash rack can prevent clogging by debris as well as prevent a person from being swept into the outlet structure and pipeline. In addition, where hydraulic conditions at the outlet structure can lead to the formation of a vortex, the design should include anti-vortex protection. It is important to note, however, that an outlet structure is not a safe structure during flood conditions, whether it is a horizontal pipe outlet or a riser type structure mounted to a horizontal pipeline. Powerful inlet velocities can draw a person underwater at the outlet structure regardless of the existence of a trash rack or grate. Signage is important to alert the public of this danger.

All site furnishings, such as benches, trash receptacles, and picnic tables must be secured to prevent them from becoming waterborne-debris which could clog the outlet structure.

Safety must also be considered downstream of outlet structures. Release flows, even though they may be controlled, can present a hazard. Specific conditions downstream of an outlet must be evaluated in terms of safety. To protect the public, structural walls shall have fencing or railing along the top of an outlet structure.

8.4.4 Safety Within the Facility

The principal factors associated with safety inside a detention/retention facility are user education, advance warning, potential water depth, slopes, routes out of flooded areas, and time to drain.

User education is a fundamental element in safety design for a detention/retention facility. Clear, concise signage with illustrative graphics can inform the public of the primary flood control purpose of the facility and describe the various features and their potential danger during a flood. Advance warning (alarms or lights triggered by upstream water levels) should be considered for multiple-use facilities, particularly where flash flooding and rapid basin inflow is possible.

Safety concerns increase with an increase in potential water depth. A facility with a potential water depth of 2 to 3 feet (less than the head height of most users) is typically less dangerous than a facility with a potential water depth of 5 to 6 feet, or more. For reasons of safety, potential water depth in detention/retention facilities should be kept to a minimum. When possible, potential water depth of three feet or less is recommended for small local detention/retention basins immediately next to residential areas.

In all facilities, regardless of depth, slopes in flood-prone areas should be kept as shallow as possible. This will allow users who find themselves caught in flooded areas (or users who deliberately enter flooded areas) to walk out and up to non-flooded zones. It is recommended that slopes in flood-prone areas not exceed 6 horizontal : 1 vertical.

In addition to slopes, consideration should be given to bottom conditions in flood-prone areas. Soils that provide firm footing when saturated are safer than soils which do not. In severe cases of unsuitable soils, partial or total removal may be necessary.

In addition to gentle slopes, routes out of flood-prone areas must be provided. Barriers that could trap a user in a flood-prone area must be avoided. Safe, well-signed exit routes that are negotiable under wet conditions must be developed.

8.5 Operation and Maintenance

There are two major components to the maintenance of a detention/retention facility. The first is to design a facility that is maintainable, and the second is the physical work required to keep the facility operating as designed and constructed. Maintenance of a detention/retention facility falls into two categories; scheduled and unscheduled. Scheduled maintenance includes those activities such as mowing, pruning, and trash removal. These activities can be predicted and can be performed on a regular basis.

Unscheduled maintenance will involve the repair of facilities after storms and flooding. The frequency and scope of this type of maintenance cannot be predicted. Some examples of unscheduled maintenance are:

1. Embankment repair to keep erosion or rock riprap or earth fill sloughing from weakening the dam structure.
2. Debris removal during and following storms.
3. Inlet and outlet channel repairs to halt erosion and maintain hydraulic capacity.
4. Inlet and outlet structure repair to insure that the facility will function as intended.

It is important that adequate funding be provided for unscheduled maintenance such that repairs can be made immediately after flood or inundation damage occurs.

The following sections outline design considerations and recommendations which facilitate maintenance of detention/retention facilities.

8.5.1 Access

Access roads for service and maintenance vehicles should be maintained to allow for equipment access to the facility, whenever needed. Access control gates should be provided if restricted access is required.

Design recommendations:

- Access ramps into the facility shall be graded at 10 percent or less. Turning radii shall be 50 feet or greater. Access ramps shall be designed for vehicle wheel capacities not less than 12,000 lbs.
- Service drives and gates shall be located in readily accessible, but inconspicuous, locations so as to not encourage unauthorized use.
- Design access control gates and adjacent areas shall be as secure as economically feasible. Initial expenditures for access control can save significant costs in future repairs.

8.5.2 Sediment Removal

Sediment will inevitably be deposited in the detention/retention facility. Conditions will be worst during years when construction activity in the watershed is greatest.

Design recommendations:

- Provide stilling basins or fore-basin collection points where most sediment will be deposited (see Section 8.7.4).
- Provide controlled vehicular access into the facility for trucks and front-end loaders.

8.5.3 Repair of Eroded Slopes

Immediate repair of eroded slopes can minimize the ultimate cost for this activity. Small areas can be repaired by hand with on-site materials. Large eroded areas are much more difficult and expensive to correct because they may require larger equipment and placement of imported material.

Design recommendations:

- Keep side slopes to minimum percentages to reduce likelihood of erosion.
- Provide vegetative or inert material cover on all slopes to minimize erosion.

- Adequately protect slopes subject to moving water or foot traffic. Make detailed evaluation of anticipated conditions and design protection accordingly. Use collector ditches for on-site drainage at the top of slopes.

8.5.4 Weed Control

Weed growth can adversely affect the use, appearance, and hydraulic characteristics of a basin. Therefore, weed growth shall be controlled.

Extensive use of herbicides in basins where the primary or secondary purpose is groundwater recharge is not acceptable.

Design recommendations:

- Plant or seed all non-paved areas in and around the basin to establish a vegetation cover. Weed infestation is much less likely in areas which have a cover of desirable plants than on disturbed or untreated areas.
- Design basins to allow all areas, including slopes, to be accessible by equipment such as flail mowers which can cut or remove weed growth.

8.5.5 Maintenance of Low Flow Channels and Drainage Structures

In-basin drainage structures and facilities must be maintained to insure their proper operation. Design can influence maintenance requirements.

Design recommendations:

- Provide access to channels for front-end loaders and hauling equipment. Provide accessible areas, free of trees, to accommodate equipment movement.
- Provide energy dissipators to prevent damage to the channel or drainage structures during high inflow conditions.
- Design structures so that they will not collect debris which could impact proper operation.

8.5.6 Landscape Maintenance

Some degree of plant and landscape maintenance will be required even when native, drought-tolerant species are planted.

Design recommendations:

- Select species with growth habits that minimize pruning and trimming or other maintenance requirements.
- Specify and use the largest plants within budgetary constraints. This can minimize potential damage during initial growth seasons.
- Space trees or plant masses for maintenance and equipment access.

8.5.7 Irrigation System Maintenance

Maintenance considerations of irrigation systems are critical, particularly when a permanent irrigation system is installed.

Design recommendations:

- Specify and use equipment that will continue to operate when “contaminated” with sand or other soil deposition. For example, large sprinkler head orifices, verses drip emitters, are less likely to clog when lake or well water is used for irrigation.
- Zone and layout system to avoid crossing channels where scour and erosion are likely to occur.
- If required, increase depth of bury or encase pipelines in concrete (particularly mainlines) that cross channels that are likely to be eroded.
- Install control equipment (other than remote control valves) in areas not subject to stormwater inundation.

8.5.8 Sign, Wall, and Fence Maintenance

For the protection of the public, informational signs and fences must be maintained and kept in good repair.

Design recommendations:

- Use signs that are made of aluminum or other durable material that does not corrode or cannot be burned.
- Secure signs to posts or standards with tamper-proof fasteners. Use posts or standards that will not be damaged by anticipated flooding or vandalism.

- Locate fences away from areas likely to collect debris and act as dams to incoming water or water moving within the basin.
- Design fences, gates, walls, etc., to minimize damage or accidental opening during normal area use or by flooding.
- In non-critical areas, design fences with an open or “clear-space” at grade to allow shallow water and debris to flow or blow under them.
- Design fences, such as backstops, with break-away or swing-away panels so flow is not impeded through the basin.

8.6 Multiple-use Concepts and Aesthetic Design Guidelines

A goal in Maricopa County is to design detention/retention facilities as amenities and, where possible, to incorporate multiple-use concepts. Flood control functions and other uses in detention/retention facilities are generally compatible. Rationale for multiple-use facilities includes decreased facility costs and an increased community acceptance. Combining flood storage with recreation uses or other community facilities on a single site decreases total costs for land acquisition and site development. The development of detention/retention facilities as parks or urban green space increases the acceptance by area residents and encourages better overall maintenance. If appropriately designed, use conflict is a minor concern.

The planning and development of facilities for multiple-use requires cooperation between the engineer, a qualified landscape architect, intergovernmental agencies, community organizations, park and recreation departments, and risk management agencies.

Appropriate uses for detention/retention facilities in Maricopa County include active and passive recreation, urban green space, water amenities, water harvesting, and groundwater recharge. Use(s) in addition to flood control should address specific community needs and be clearly identified before the facility is designed.

8.6.1 Active Recreation

Active recreation includes a wide range of organized and unstructured activities that involve some type of physical movement. This type of recreational activity—both individual and group—generally requires larger areas than passive recreation uses. Because of their size, regional detention/retention facilities can provide more opportunities for group sports with large space requirements. Field sports (soccer, football, baseball) require areas with standardized dimensions.

8.6.2 Passive Recreation

Passive recreation generally involves individuals or small groups and a minimal amount of physical activity. Typically, passive recreation does not require large open spaces, and is, therefore, appropriate for both large and small detention/retention facilities.

8.6.3 Detention/Retention Facilities as Water Amenities

Facilities that incorporate a permanent pool can provide physical and psychological relief from the hot desert environment. The use of a permanent pool for detention/retention facilities is limited strictly to a visual amenity because body contact activities, such as swimming or wading, are specifically excluded.

8.6.4 Urban Green Space

Urban green space provides a visual resource within the community. As urbanization continues, the value of green space will increase. Green space provides visual breaks from the urban environment, acts as a filter to clean the air and can reduce erosion from wind and rain. Landscape materials in a detention/retention facility should respond to the recessed nature of the land form, the scale of the facility and the occurrence of frequent flooding.

The use of native and non-native, drought-tolerant species for landscape planting is highly recommended. The following basic zones should be considered in the landscape design for a detention/retention facility.

Channels: These are areas where there will be flowing water. Planting in these areas should be limited to grasses, groundcovers and low growing shrubs, with preference given to vegetation with flexible branching and resilient growth habits.

Basin Areas: There may be inundation and standing water in basin areas at some time during the year. Choice of plant materials should reflect these conditions. Trees, shrubs and grasses can be planted judiciously in these zones.

Elevated Areas: These areas may be occasionally inundated. The choice of plant material will depend on the use assigned to the area. Trees, shrubs and grasses can be planted and more easily maintained in areas of higher ground elevation.

8.6.5 Water Harvesting for Reuse or Recharge

A basic water harvesting system consists of three components: collection, storage and dispersion. Since stormwater detention/retention facilities will already be designed to collect and store runoff, some simple additions may allow harvesting the water for reuse.

All applicable requirements of the Health Department and the Arizona Department of Water Resources must be met in addition to the normal review requirements.

When reusing stormwater for such things as on-site landscape irrigation, the facility must be lined by an impermeable membrane or by treating the soils to increase impermeability with native or imported clay or other measures. The local jurisdiction must be contacted regarding the acceptability of soil treatment measures in terms of the effect on water quality. Grading of the surrounding site should optimize runoff to the storage facility. An evaporation control mechanism may be appropriate for a surface storage system. Dispersion of water is typically achieved by pumping from the pond for irrigation.

A facility may be designed specifically to augment the groundwater aquifer. No formal dispersion is required other than methods to maximize the potential for water to percolate through the subsurface to the groundwater table. Thus, the facility should be designed to maximize the surface contact area between the stored water and the soil. Potential siltation problems must be addressed by providing a settling basin at the inlet or by other suitable measures.

Runoff water stored for recharge or reuse purposes does not contribute to detention/retention requirements. Adequate storage for detention/retention must be provided at all times, in addition to the volume provided for harvesting water.

8.7 Water Quality

8.7.1 Introduction

Urban runoff is distinguished from undeveloped area runoff in two principal ways: it occurs at greater discharge rates and volumes, and it contains varying but commonly higher concentrations of toxic substances, bacteria, and dissolved organic matter. Detention/retention facilities can play a significant role in mitigating the pollution problems associated with urban runoff.

8.7.2 Major Pollutants and Their Sources

Major pollutants associated with urban runoff include the following:

Sediment: Construction activities associated with urbanization and poor agricultural practices result in erosion and sedimentation.

Suspended Materials: Particulate matter and floating material, such as oils and scum, are included as suspended material. Suspended solid concentration in urban runoff may be 2 to 3 times that found in domestic waste.

Oxygen Demanding Materials: These include degradable organic matter and certain nitrogen compounds that consume the available dissolved oxygen as they degrade. The biochemical oxygen demand of stormwater runoff is usually in the 20 to 30 mg/l range, almost the same range as sewage effluent after secondary treatment.

Pathogenic Bacteria and Viruses: These include coliform, fecal coliform, and fecal streptococci, the same pathogenic bacteria and viruses found in domestic sewage.

Toxic Substances: These include heavy metals and a full range of EPA designated pollutants. The EPA list contains approximately 100 primarily organic substances, such as TCE.

Studies show that the areas contributing the greatest amounts of pollution are those with highly erodible surface conditions, such as plowed land or construction sites, or those areas characterized by highly impermeable surfaces, such as shopping malls, industrial areas and large housing complexes. Runoff from vehicular right-of-way (which accounts for over 20 percent of some urban lands), will contain hydrocarbons, other organics, and a diminishing—but still significant—amount of lead. Fertilizers and pesticides are transported by runoff from residential and agricultural areas.

8.7.3 Role of Detention/Retention Facilities in Water Quality Control

Most pollutants of concern have a high affinity for suspended solids in runoff and for soil particles. Thus, the most logical way to achieve pollutant removal is through sedimentation and infiltration. Consequently, detention/retention facility design for water quality control should maximize settling to the extent possible. This consideration may alter typical design features. In general, quiescent conditions and infiltration should be maximized while short-circuiting should be minimized. Design techniques that will accomplish these objectives are:

- Using long, narrow basin configurations, i.e., length to width ratios of 2:1 to 3:1, with the length measured along a line between the inlet and outlet.
- Installing inlet and outlet structures at extreme ends of the basin.
- Using baffles or flow retarders.
- Constructing ponds in two stages.
- Using riser outflow structures instead of ground level pipes to maintain a slow-draining pool encouraging infiltration.

- Developing a grass cover for the basin floor.
- Using underground tile drains for outlet discharge to provide soil filtration of the runoff.

Using wet rather than dry ponds will generally improve quiescent conditions, maximize infiltration, and provide a degree of biological treatment.

8.7.4 Method for Control of Sedimentation

Sediment removal within a detention/retention facility may be facilitated by the use of a “sediment trap” at the inlet, which will concentrate the majority of the incoming sediment bed load to a small portion of the facility. Sediment traps should be provided in conjunction with all detention/retention facilities which are intended as multi-use facilities. Figure 8.10 is a conceptual sketch of a typical detention basin sediment trap. The following list provides guidelines for the design of efficient sediment traps.

1. An additional sedimentation volume should be provided within the sediment trap at an elevation below the invert of the inflow channel.
2. The length/width ratio of the sediment trap should be a minimum of 2:1, with the length measured along a line between the inlet and outlet.
3. The basin shape should be wedge-shaped, with the narrow end located at the inlet to the basin (see Figure 8.10).
4. Provisions for total drainage and accumulated sediment removal of the sediment trap must be provided. Maintenance access should also be provided and designed to accommodate heavy trucks and other equipment necessary for removal of accumulated sediment.

8.8 Flood Routing

8.8.1 Flood Routing through Detention Facilities by the Storage-Indication Method

Characteristically, the storage of a reservoir is closely related to its outflow rate. In reservoir routing methods, the storage-discharge relation is used for repeatedly solving the continuity equation; each solution is a step delineating the outflow hydrograph.

Section

Figure 8.10
Sediment Trap Concept

(Pima County Department of Transportation and Flood Control District)

Numerous computer software programs (such as HEC-1) have been developed for flood routing through detention/retention facilities. Use of a particular computer program should be approved by the appropriate jurisdictional agency prior to its application on a particular project.

The continuity equation used in reservoir routing methods is concerned with conservation of mass: for a given time interval, the volume of inflow minus the volume of outflow equals the change in volume of storage. The continuity equation for a reservoir is:

$$\frac{dS}{dt} = I(t) - O(t) \quad (8.2)$$

If the time is broken into intervals of duration and indexed by j , Equation 8.2 can be rewritten for the change in storage over the interval:

$$S_{j+1} - S_j = \frac{I_j + I_{j+1}}{2} \Delta t - \frac{O_j + O_{j+1}}{2} \Delta t \quad (8.3)$$

The values of I_j and I_{j+1} are obtained from an inflow hydrograph. The values of O_j and S_j are obtained at the j th time interval from calculation during the previous time interval. Equation 8.4 results from multiplying Equation 8.3 through by $2/\Delta t$ and by isolating the unknowns O_{j+1} and S_{j+1} :

$$\left(\frac{2S_{j+1}}{\Delta t} + O_{j+1}\right) = (I_j + I_{j+1}) + \left(\frac{2S_j}{\Delta t} - O_j\right) \quad (8.4)$$

Equation 8.4 can be used to facilitate the storage-outflow function solution in tabular form (see sample problem, Section 8.8.2). In order to calculate the outflow (O_{j+1}) from Equation 8.4, a storage outflow function relating $2S/\Delta t + O$ and O is needed. The method for developing this relationship using elevation-storage and elevation-outflow data is shown in Figure 8.11.

Figure 8.11
Development of the Storage-Outflow Function for Level Pool Routing
on the Basis of Storage-Elevation and Elevation-Outflow Curves

(From: Applied Hydrology, Chow et al 1988)

The following steps are used in the Storage-Indication Method of flood-routing:

1. Develop the inflow hydrograph (refer to the *Drainage Design Manual for Maricopa County, Volume I, Hydrology*, FCD).
2. Develop a elevation-storage relationship (Figure 8.11a) for the structure. The storage will normally be developed in acre-feet which will then be converted to cubic feet in the working table (see Table 8.3).
3. Develop a elevation-discharge relationship (Figure 8.11b) for the structure from hydraulic equations relating head and discharge for various types of spillways and outlet works. Table 8.2 includes equations that can be used. For a discussion on the values of C , C_o , and C_d , see *Design of Small Dams* (USBR 1987).

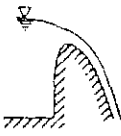

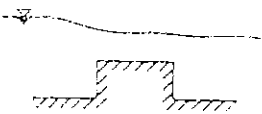

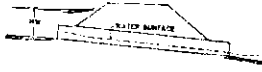

4. Select the routing interval, Δt . The shorter the interval selected, the more precise the results will be.
5. Using the results of steps 2 and 3, make a four-column table with the following headings: (1) Elevation H , ft; (2) Storage S , ft³; (3) Discharge O , cfs; and (4) $2S/\Delta t + O$. For an example, see Table 8.5.
6. Plot the value of $2S/\Delta t + O$ on the horizontal axis of a graph with the value of the outflow, O , on the vertical axis (see Figure 8.11c). Figure 8.12, page 8-47, represents such a graph.
7. Compute the value of $(2S_{j+1}/\Delta t) + O_{j+1}$ using Equation 8.4. All of the terms on the right side of Equation 8.4 are known for time interval j . Obtain the values of I_j and I_{j+1} from the inflow hydrograph (Step 1), as is done in Table 8.6.
8. Determine the corresponding value of O_{j+1} to $(2S_{j+1}/\Delta t) + O_{j+1}$ from the storage-outflow relationship $(2S/\Delta t) + O$ versus O (Figure 8.12). This can be done by either using the plot of step 6 or by linear interpolation of tabular values from step 5.
9. Calculate the value of $(2S_{j+1}/\Delta t) - O_{j+1}$ to set up the data required for the next time interval by:

$$\left(\frac{2S_{j+1}}{\Delta t} - O_{j+1}\right) = \left(\frac{2S_{j+1}}{\Delta t} + O_{j+1}\right) - 2O_{j+1} \quad (8.5)$$

10. Repeat the computation for subsequent routing periods and plot the inflow and outflow hydrographs. See Figure 8.13.

Steps 7, 8, and 9 are demonstrated in Table 8.6. With the exception of Step 8, all of these steps can be easily performed by using a spreadsheet.

Table 8.2
Spillway Discharge Equations
 (from: Applied Hydrology, Chow et al 1988)

Spillway Type	Equation	Notation
Uncontrolled overflow ogee crest 	$O = CLH^{3/2}$	O = Discharge, cfs C = Discharge Coefficient ⁽¹⁾ L = Effective length of crest H = Total head on the crest including velocity approach head
Broad-crested weir 	$O = C_o LH^{3/2}$	O = Discharge, cfs C _o = Discharge coefficient ⁽²⁾ L = Effective length of crest H = Total head on the crest including velocity of approach head
Culvert (submerged inlet control) 	$O = C_d A \sqrt{2gH}$	O = Discharge, cfs C _d = Discharge coefficient ⁽³⁾ A = Cross-sectional area g = Acceleration due to gravity, 32.2 ft/s ²

- (1) C value for ogee crest varies from 3.1 to 3.9 depending upon the head, the depth of approach, the slope of the upstream face, and the configuration of the downstream apron.
- (2) C_o value for broad-crested weir varies from 2.3 to 3.3 depending upon the head, the breadth of the weir crest, and the shape of the upstream corner.
- (3) C_d value for a culvert varies from 0.2 to 0.9 depending upon the head, pipe size, pipe length, material of the pipe, and the shape of the inlet edge.

8.8.2 Flood Routing Sample Problem

A detention basin is proposed. Determine the peak outflow discharge and the peak water surface elevation in the basin.

Given:

1. Inflow Hydrograph (plotted on Figure 8.13).

Time, hrs	Inflow, cfs	Time, hrs	Inflow, cfs
0.00	0	2.00	250
0.25	10	2.25	160
0.50	25	2.50	110
0.75	50	2.75	70
1.00	100	3.00	40
1.25	220	3.25	20
1.50	610	3.50	10
1.75	450	3.75	0

2. Stage-Surface Area Relationship.

Elevation, ft	Surface Area, Acres
1100	4.6
1100.5	4.8
1101	5.2
1101.5	5.4
1102	5.6
1103	5.8
1104	6.2
1105	6.6
1106	7.0
1107	7.5
1108	7.8

3. Outflow Structures

a. Principal Spillway, ogee crest

Discharge coefficient = 3.5

Width of weir = 20 ft

Elevation of weir crest = 1104 ft

b. Low Flow Structure, culvert (corrugated metal pipe)

Discharge coefficient = 0.5

Diameter = 15 inches = 1.25 ft

Elevation of culvert inlet = 1100 ft

Elevation of culvert center = 1100.63 ft (used to determine H_2)

Solution:

Step 1. An inflow hydrograph for this sample problem is given, so the solution procedure begins with Step 2. However, for a practical problem, the inflow hydrograph needs to be developed for Step 1.

Step 2. Develop a Water Surface Elevation-Storage Relationship, as in Table 8.3.

Table 8.3
Water Surface Elevation-Storage Relationship

Elevation	Surface Area, Acres	Average Surface Area, Acres	Difference in Elevation, ft	Interval Storage Acre-ft	Storage, Acre-ft	Storage, ft ³
1100.0	4.6				0	0
		4.7	0.5	2.35		
1100.5	4.8				2.35	102,370
		5.0	0.5	2.5		
1101.0	5.2				4.85	211,270
		5.3	0.5	2.65		
1101.0	5.4				7.5	326,700
		5.5	0.5	2.75		
1102.0	5.6				10.25	446,490
		5.7	1.0	5.7		
1103.0	5.8				15.95	694,780
		6.0	1.0	6.0		
1104.0	6.2				21.95	956,140
		6.4	1.0	6.4		
1105.0	6.6				28.35	1,234,930
		6.8	1.0	6.8		
1106.0	7.0				35.15	1,531,130
		7.25	1.0	7.25		
1107.0	7.5				42.4	1,846,940
		7.65	1.0	7.65		

Step 3. Develop a Water Surface Elevation-Discharge Relationship, as in Table 8.4

Weir Flow

$$O_1 = C_1 L H_1^{3/2} = (3.5)(20) H_1^{3/2}$$

Culvert Flow

$$O_2 = C_2 A \sqrt{2gH_2} = (0.5) \frac{(3.14)(1.25)^2}{4} \sqrt{(2)(32.2)(H_2)}$$

Total Outflow

$$O = O_1 + O_2$$

Table 8.4
Water Surface Elevation-Discharge Relationship

Water Surface Elevation	Weir		Culvert		Total Discharge, cfs
	H ₁	O ₁	H ₂	O ₂	
1100.0	0	0	0	0	0
1100.5	0	0	0	0	0
1101.0	0	0	0.37	3	3
1101.5	0	0	0.87	5	5
1102.0	0	0	1.37	6	6
1103.0	0	0	2.37	8	8
1104.0	0	0	3.37	9	9
1105.0	1	70	4.37	10	80
1106.0	2	198	5.37	11	209
1107.0	3	364	6.37	12	376
1108.0	4	560	7.37	13	573

Step 4. $\Delta t = 0.25 \text{ hrs} = 900 \text{ seconds}$

Step 5. Develop a Storage-Outflow Relationship for a detention reservoir, as in Table 8.5

Table 8.5
Storage-Outfall Relationship
for a Detention Reservoir

Elevation H, ft	Storage S, ft ³	Discharge O, cfs	(2S/ Δt) + O, cfs
1100.0	0	0	0
1100.5	102,370	0	227
1101.0	211,270	3	472
1101.5	326,700	5	731
1102.0	446,490	6	998
1103.0	694,780	8	1,552
1104.0	956,140	9	2,134
1105.0	1,234,930	80	2,824
1106.0	1,531,130	209	3,612
1107.0	1,846,940	376	4,480

Pump Stations

9.1 Introduction

Stormwater pump stations are used where gravity discharge is not feasible or for metering flow out of detention/retention facilities. When used independently of a detention/retention facility, storage should be incorporated into pump station facilities to reduce pump cycling and hence the initial capital and long-term operational costs of the pump station.

The actual design of pump stations involves several technical disciplines, and the approach to the design is often dependent on the size of the facility and the consequences of any type of system failure. A pumping facility failure serving a major interchange and adjacent major development causing millions of dollars of damages demands greater reliability than a small pumping facility that drains a retention pond with a 36-hour disposal time and overflows result in small increases in water depth of an adjacent street. This chapter provides only an overview of the conditions that should be considered in the design of stormwater pumping facilities.

Stormwater pump stations may be either dry pit or wet pit facilities. In the latter type of facility, the pumps are submersible and are located in a wet well. In the former type, centrifugal pumps are located in a dry pump room and generally use a wet well to modulate the incoming flows (a form of storage). For small pump stations, the pump may be located in an inlet or a manhole-type wet well.

For a rigorous discussion of the design of stormwater pump stations, refer to *Manual for Highway Stormwater Pumping Stations* (FHWA, 1982).

9.2 Design Approach

The design approach addresses two conditions, the criteria that are to be applied and a check list of conditions that should be considered in the design of pumping facilities (see Table 9.1).

Criteria: The use of pumping facilities for stormwater is discouraged and will be considered only on express agreement by the jurisdictional agency. Unless exempted by the jurisdictional agency, the following criteria should be applied to the design of stormwater pump stations:

1. Pumping facilities (excluding components whose design requires submersion) will be set at an elevation at or above the anticipated level of the 100-year event, considering that a total power failure may occur.
2. Pumps shall be capable of handling solids up to a minimum of 3-inches. Consideration for handling smaller solids can be made for pumping facilities that serve storage facilities.
3. Screening devices will not be used at the entrances to the pump stations. Grates will be used on each catch basin.
4. Required calculations include: a) total dynamic head; b) net positive suction head; c) head capacity curves (parallel operation); and d) mass flow curves.
5. Controls will provide for automatic and manual operations and will have communications to permit transmission of failure signals to designated reporting locations.
6. A potable water supply with back-flow prevention and hose bibs should be provided to aid in removal of silt and trash.
7. A ventilation system will provide intermittent ventilation of wet-wells.
8. Plugging factors will be used on inlets of pipe systems that are tributary to pump stations.
9. Facilities not associated with retention facilities will provide storage to the maximum practical extent to aid in efficient operation of the system.
10. A redundant pumping system may be required, particularly at small installations.
11. The site layout shall consider adequate access for maintenance vehicles.
12. Generally, stormwater pump stations should not be privately maintained.

Glossary

1/2 PMF: The flood hydrograph with ordinates equal to one-half the corresponding ordinates of the Probable Maximum Flood Hydrograph.

100-Year Flood: A flood stage or height that, statistically, has one percent chance of being equaled or exceeded in any given year. The 100-year flood is often referred to as the base flood.

Abutments: Walls supporting the end of a bridge or span, and sustaining the pressure of the abutting earth. In a drop structure, the walls which form the sides of the crest of the drop. In some structures, wingwalls (transition walls) extend upstream of the abutment walls to create a smooth transition from the upstream channel.

Aggradation: A progressive buildup or raising of the channel bed due to sediment deposition. Permanent or continuous aggradation is an indicator that a change in the stream's discharge and sediment load characteristics is taking place, see Degradation.

Alluvium: Unconsolidated material deposited by a stream in a channel, floodplain, alluvial fan, or delta.

Armor: Surfacing of channel bed, banks, or embankment slope to resist erosion.

Armoring: (a) Natural process whereby an erosion-resistant layer of relatively large particles is formed on a streambank due to the removal of finer particles by streamflow. (b) Placement of a covering on a streambank to prevent erosion.

Arterial Street System: The arterial system should carry a major portion of trips entering and leaving the urban area, as well as the majority of movements through the central city. Frequently, the arterial system will carry important intra-urban as well as intercity bus routes. Arterials are typically located on one-mile intervals on section lines.

Baffle Chute: A type of drop structure or outlet structure that incorporates baffles for energy dissipation.

Baffles: Deflector vanes, blocks, guides, grids, gratings or similar devices constructed to: 1) check or effect a more uniform distribution of velocities; 2) dissipate energy; 3) divert, guide, or agitate flow; and 4) check eddy currents.

Basin Area: The area which contributes stormwater to a concentration point such as a lake, stream, or drainage system. See Watershed.

Basin Floor: The bottom of a stormwater retention facility which has been specifically designed for the purpose of disposing stored runoff following a storm event by the process of infiltration into the subsurface.

Basin Sediment Yield: The total sediment outflow from a watershed or a drainage area at a point or reference and in a specified time period. This outflow is equal to the sediment discharge from the drainage area.

Bed Material: Material found on the bed of a stream (may be transported as bed load or in suspension).

Bed Sediment Discharge: The part of the total sediment discharge that is composed of grain sizes found in the bed and is equal to the transport capability of the flow.

Braided Stream: A stream whose flow is divided at normal stage by small mid-channel bars or small islands; the individual width of bars and islands is less than about three times the water width; a braided stream has the aspect of a single large channel within which are subordinate channels.

Bridge Low-chord: The elevation of the lowest portion of the bridge deck structure used in determining the area of the bridge opening available for flow conveyance.

Catch Basin: A chamber or well, usually built at the curb line of a street, for the admission of surface water to a storm sewer or sub-drain.

Channel Failure: Sudden collapse of a channel due to an unstable condition, such as the removal of a bank by scour.

Channel Reach: A segment of stream length that is arbitrarily bounded for purposes of study.

Channel Stabilization: Methods of achieving slope and cross-section which allow a channel to transport the water and sediment delivered from the upstream watershed without aggradation or streambank erosion.

Check Dam: A low dam or weir across a channel, for the diversion of irrigation. Also used herein for a low dam to control stream gradient, typically associated with small streams or the low flow channel of a floodplain or other channel.

Check Structure: A small drop structure constructed in the low flow portion of a channel for the purpose of controlling stream gradient.

Clear Zone: The roadside border area, starting at the edge of the traveled way, available for safe use by errant vehicles.

Clear-water Scour: Scour which occurs when there is no movement of the bed material of the stream upstream of the crossing, but occurs as a result of acceleration of the flow and vortices created by piers or abutments causing material at their base to move.

Collector Street System: Collector streets may penetrate neighborhoods and may carry a minor amount of through traffic.

Contraction Scour: General scour resulting from the acceleration of flow due to a natural channel constriction or bridge contraction.

Crest: That portion of the drop structure which controls the gradient of the upstream channel. In a vertical drop structure the crest is a wall typically constructed of reinforced concrete or sheet pile. In a sloping drop structure, the crest is the portion of the drop at the top of the slope and usually incorporates a buried cutoff wall for seepage control.

Critical Depth: The depth at which a given discharge flows in a given channel with a minimum specific energy. For depths greater and lower than critical, the flow is said to be subcritical and supercritical, respectively.

Critical Flow: Flow at critical depth.

Culvert: A hydraulically short conduit which conveys surface water runoff through a roadway embankment or through some other type of flow obstruction. Culverts are constructed from a variety of materials and are available in many different shapes and configurations. Culvert selection factors include roadway profiles, channel characteristics, flood damage evaluations, construction and maintenance costs, and estimates of service life.

Degradation: A progressive lowering of the channel bed due to scour. Permanent or continuing degradation is an indicator that a change in the stream's discharge and sediment load characteristics is taking place, see Aggradation.

Design Discharge: Maximum flow a structure or channel is expected to accommodate without contradicting the adopted design constraints.

Detention Basin: A basin or reservoir where water is stored for regulating a flood. It has gravity-flow outlets for outflows during floods.

Design Frequency: The nth-year storm for which it is expected that the structure or facility designed for that storm would experience an actual hydrological event of a given or greater magnitude, once, on average, in n years. For example, a 50-year storm has a 2 percent chance of occurring in any given year. Also called the return period, exceedence interval, or recurrence interval.

Discharge: Volume of water passing through a channel during a given time.

Drainage Basin: A geographical area which contributes surface runoff to a particular concentration point. The terms "drainage basin", "tributary area" and "watershed" are used interchangeably.

Drainageway: A route or watercourse along which storm runoff moves, or may move, to drain a catchment area.

Drop Structure: A structure constructed in a conduit, canal, or open channel for the purpose of gradient (bottom slope) control.

Dry Well: An engineered subsurface chamber designed to accept surface runoff and allow it to drain into the subsurface strata.

Embankment: A man-made earth fill structure constructed for the purpose of impounding water.

Emergency Spillway: An outflow spillway from a stormwater detention/retention facility that provides for the safe overflow of floodwaters for storm events in excess of the design capacity of the Primary Outlet Structure, or in the event of malfunction or debris blockage of the Primary Outlet Structure.

Energy Grade Line (EGL): An inclined line representing the total energy of the flowing water. For an open channel, the EGL is above the **water surface** by a value of the velocity head. In a closed pressure conduit, the EGL is above the **pressure head line** by a value of the velocity head. See Hydraulic Grade Line and Figure 4.3.

Equilibrium: The state of balance of natural channels between hydraulic forces or actions. Equilibrium occurs when the streambed has achieved a graded condition when the slope and energy of the stream are just sufficient to transport material delivered to it. Natural channels which have small changes resulting from periods of low and high flows are considered in equilibrium.

Erosion: Displacement of soil particles on the land surface due to water or wind action.

Filter: Layer of fabric, sand, gravel, or graded rock placed (or developed naturally where suitable in-place materials exist), between the bank revetment and soil for one or more of three purposes: 1) to prevent the soil from moving through the revetment by piping, extrusion, or erosion; 2) to prevent the revetment from sinking into the soil; and 3) to permit natural seepage from the streambank, thus preventing buildup of excessive hydrostatic pressure.

Filter Blanket: A layer of graded, intermediate-size gravel placed between fine-grained material and riprap, to prevent wash-out of the finer material.

Filter Fabric: Fabric of synthetic strands that serves the same purpose as granular filter blanket.

Fine Sediment Load (or Washload): That part of the total sediment load that is composed of particle sizes finer than those represented in the bed. Normally, the fine-sediment load is finer than 0.062 mm for a sand-bed channel. Silt, clay, and sand could be considered fine sediment load in a coarse gravel and cobble bed channel. The washload generally comes from the watershed.

Flood Fringe: A regulatory district within the floodplain but outside the floodway district.

Flood Peak: The largest value of the runoff flow which occurs during a flood event, as observed at a particular point in the drainage basin.

Flood Routing: The mathematical simulation of a flood wave as it moves downstream along a watercourse or through a detention/retention facility.

Floodplain: A flood-prone area of land adjoining or near the channel of a watercourse which have been, or may be, covered by floodwaters. A floodplain functions as a temporary channel or reservoir for overbank flows.

Floodway: A specific regulatory district within the floodplain as identified on FEMA flood hazard boundary maps; or the channel of a river or other watercourse and the adjacent land area necessary to discharge the 100-year flood without cumulatively increasing the water surface by more than one foot and without creating hazardous velocities of floodwaters.

Freeboard: The vertical distance above a design water surface elevation that is provided as a contingency or allowance for waves, surges, water-borne debris or other factors.

Froude Number: A dimensionless number (expressed as $V/(gy)^{0.5}$) that represents the ratio of inertial to gravitational forces. High Froude numbers (values greater than 1) indicate supercritical flow with associated high velocity and scour potential.

Gabion or Wire-Enclosed Basket: A basket or compartmented rectangular container made of steel wire mesh. When filled with cobbles or rock of suitable size, the gabion becomes a flexible and permeable block with which flow-control structures can be built.

General Scour: Scour in a channel or on a floodplain that is not localized at a pier, abutment, or other obstruction to flow. In a channel, general scour usually affects all or most of the channel width.

Geomorphology: That branch of both physiography and geology that deals with the form of the earth, the general configuration of its surface, and the changes that take place due to erosion of the primary elements and in the buildup of erosional debris.

Grade Control Structure (sill, check dam): A structure across a stream channel placed bank to bank (usually with its central axis perpendicular to flow) to control bed slope and prevent scour or headcutting.

Gradient: The rate of change of a characteristic per unit of length. The term is usually applied to such things as channel/stream bed slope elevation, conduit invert elevation, velocity, pressure, etc.

Guide Bank: A dike extending upstream from the approach embankment at either or both sides of the bridge opening to direct the flow through the opening. Some guide banks extend downstream from the bridge.

Gunite: Term formerly used for dry-mix mortar shotcrete.

Headcutting: Channel bottom erosion moving upstream along a waterway indicating that a readjustment of the channel's slope and its discharge and sediment load characteristics is taking place. Headcutting is evidenced by the presence of abrupt vertical drops in the stream bottom or rapidly moving water through an otherwise placid stream. Headcutting often leaves stream banks in an unstable condition as it progresses along the channel.

Hydraulic Grade Line (HGL): For an open channel, it is coincident with the water surface. In a closed pressure conduit, it is the line representing the pressure head of the conduit. HGL will always be EGL minus the velocity head. See Energy Grade Line and Figure 4.4.

Hydraulic Jump: The hydraulic jump is an abrupt rise in the water surface which occurs in an open channel when water flowing at supercritical velocity is retarded by water flowing at subcritical velocity or a stationary pool. The transition through the jump results in a marked change in energy, evidenced by turbulence of the flow within the area of the jump. The hydraulic jump is often used as a means of energy dissipation.

Hydraulic Structures: The facilities used to impound, accommodate, convey or control the flow of water, such as dams, weirs, intakes, culverts, channels, and bridges.

Hydrograph: The functional relationship between time and flow discharge, as observed at a particular point within a drainage basin. In the case of a detention/retention facility, an Inflow Hydrograph depicts the relationship of time and runoff inflow to the facility, and an Outflow Hydrograph is a graph of flow discharge from the facility versus time.

Impervious: A term applied to a material through which water cannot pass, or through which water passes with great difficulty.

Incised Stream: A stream that flows in an incised channel with high banks. Stream banks that stand more than 15 feet above the water surface at normal stage are regarded as high banks.

Infiltration: The movement of water into and through the soil.

Invert: The lowest point in the channel cross section or at flow control devices such as drop structures, dams, or outlet structures, see Thalweg.

Jurisdiction or Jurisdictional Agency: Maricopa County, the Flood Control District of Maricopa County, and the incorporated municipalities within Maricopa County.

Lateral Stream Migration: Change in position of a channel by lateral erosion of one bank and simultaneous accretion of the opposite bank. Movement in which the material has a dominate lateral component.

Launching: Release of undercut material (stone riprap, rubble, slag, etc.) downslope; if sufficient material accumulates on the streambank face, the slope can become effectively armored.

Live-bed Scour: Scour which occurs when the bed material upstream of the crossing is also moving.

Local Aggradation: Aggradation in a channel or on a floodplain that is localized at a pier, abutment, or other obstruction to flow.

Local Scour: Scour in a channel or on a floodplain that is localized at a pier, abutment, or other obstruction to flow.

Local Street System: The local street system comprises all facilities not on one of the higher systems. It offers the lowest level of mobility and usually contains no bus routes. Service to through traffic movement usually is deliberately discouraged.

Low Flow Channel: A channel within a larger channel which typically carries low and/or normal flows.

Major drains: Include natural and man-made channels and conduits that serve watershed areas from 160 acres to about 10 square miles.

Master Planning: A "systems" approach to the planning of facilities, programs and management organizations for comprehensive control and use of stormwater within a defined geographical area or drainage basin.

Meandering Channel: A channel exhibiting a characteristic process of bank erosion and point bar deposition associated with systematically shifting meanders.

Median Diameter: The particle diameter at the 50 percentile point on a size distribution curve such that half of the particles (by weight for samples of sand, silt or clay and by actual measurement for samples of gravel and riprap) are larger and half are smaller. The median diameter is denoted D_{50} .

Minor drains: Serve watershed areas up to 160 acres and are normally the drains associated with subdivision development.

Multi-purpose Facility: A detention or retention facility that provides benefits in addition to the primary function of flood control. Such benefits may include recreation, parking, visual buffers or water harvesting.

Nappe: The sheet or curtain of water overflowing a weir or dam. When freely overflowing the crest of a structure, it usually has a well-defined upper and lower surface.

Off-stream Detention/Retention Facility: A facility that is located near or adjacent to a watercourse (i.e., the stream does not flow directly into the facility). Inflow to the facility is typically accomplished by means of side weirs. It is also referred to as an Off-line Detention/Retention Facility.

On-site Detention/Retention: The temporary storage of excess storm runoff in the upper area of a drainage basin. This type of facility is typically within a subdivision, primarily by an individual development and generally irrespective of watershed features.

On-stream Detention/Retention Facility: A facility that is located within the path of a stream or watercourse, and thereby intercepts the entire flow from the upstream drainage basin. It is also referred to as an On-line Detention/Retention Facility.

Orifice: A hole in the outlet structure of a stormwater storage facility sized to drain the facility at a specific rate of flow.

Outlet Structure: A hydraulic structure placed at the outlet of a conduit, open channel, spillway, etc., for the purpose of dissipating energy and providing a transition to the channel or conduit downstream. Outlet structures may consist of culverts, weirs, orifices (gated or un-gated), dry wells, or any combination thereof.

Plunge Pool: An energy dissipation device placed downstream of a conduit, channel or vertical wall drop structure. The plunge pool basin is typically lined with rock riprap, concrete or other protective covering and dissipates the energy of free falling water through impact and turbulence.

Pressure Head: In a closed pressure conduit, it represents the energy per unit weight stored in the fluid by virtue of the fluid being under pressure expressed as P/γ . Generally having the units of feet. In an open channel, the pressure head is zero.

Primary Outlet Structure: Also known as the Primary Spillway or Principal Spillway, it is the main outlet structure by which stormwater is discharged from the detention/retention facility.

Probable Maximum Flood (PMF): The flood runoff that may be expected from the most severe combination of critical meteorologic and hydrologic conditions that are reasonably possible in the region.

Pump Station: A facility housing stormwater pumps, controls, power plants and their appurtenances.

Regional Detention/Retention: The temporary storage of excess runoff by means of large storage facilities located at strategic sites within a drainage basin. Sites are generally planned to provide control of excess runoff from an entire drainage basin with an optimum (presumably a minimum) number of storage facilities to achieve the most cost-effective drainage system. Regional detention/retention sites are normally maintained by a public or quasi-public agency.

Regional drains: The main outfalls for drainage. They serve watershed areas generally greater than 10 square miles, and include rivers and washes.

Residual Freeboard: For an embankment dam, the vertical distance between the maximum water surface elevation and the minimum dam crest elevation.

Retention Basin: A basin or reservoir wherein water is stored for regulating a flood, however, it does not have gravity-flow outlets for outflows during floods as detention basins do. The stored water must be disposed by some other means such as by infiltration into soil, evaporation, injection (or dry) wells, or pumping systems.

Reverse Filter Drain: An engineered granular filter placed at weep hole locations on hydraulic structures to collect and direct groundwater to the weep holes to relieve uplift pressures and other adverse effects of uncontrolled seepage water.

Riprap Toe Protection: In the restricted sense, layer or facing of broken rock or concrete dumped or placed at the toe of a channel to protect a structure or embankment from erosion; also the broken rock or concrete suitable for such use. Riprap has also been applied to almost all kinds of armor, including wire-enclosed riprap, grouted riprap, sacked concrete, and concrete slabs.

Runoff: The portion of precipitation on land that ultimately reaches streams; especially water from rain or melted snow that flows over the ground surface.

Scour: Erosion due to flowing water, usually considered as being localized as opposed to general bed degradation.

Sediment (or Fluvial Sediment): Fragmental material transported, suspended, or deposited by water.

Sediment Discharge: The quantity of sediment that is carried past any cross section of a stream in a unit of time. Discharge may be limited to certain sizes of sediment or to a specific part of the cross section.

Sediment Trap: An area within a stormwater detention/retention facility which is designed to trap the majority of incoming sediments for the purpose of facilitating maintenance.

Seepage: The movement of water through pores and voids of pervious material such as soil, gravel, synthetic filter media, etc.

Seepage Cutoff Wall: An impervious subsurface barrier constructed of clay, concrete or synthetic material for the purpose of increasing the length of travel of subsurface water flow and thereby reducing and/or controlling the action of such flows (for example, uplift forces) at hydraulic structures.

Shotcrete: Mortar or concrete pneumatically projected at high velocities onto a surface.

Sill: A raised edge at the downstream end of a stilling basin. The sill typically has a notch or opening to allow normal stream flows to pass through and/or to allow the basin to drain completely following a storm.

Slope Paving: Covering of a channel bank or bed with stones or concrete.

Soil-Cement: A designed mixture of soil and portland cement compacted at a proper water content to form a veneer or structure which when placed on a streambed or bank can prevent erosion. Also referred to as Cement Stabilized Alluvium.

Spillthrough Abutment: A bridge abutment having a fill slope on the streamward side.

Spillway: (a) A low-level passage serving a dam or reservoir through which surplus water may be discharged; usually an open ditch around the end of a dam, or a gateway or a pipe in a dam. (b) An outlet pipe, flume, or channel serving to discharge water from a ditch, ditch check, gutter or embankment protector.

Stage: The depth of water within a stormwater storage facility, as measured above an established datum.

Storage Reservoir of Pump Station: A reservoir wherein peak flows from storm drains are stored for reducing capacity requirements of the pump station to pump runoff to an appropriate outlet.

Storm Drainage System: A drainage system for collecting runoff of stormwater on highways and removing it to appropriate outlets. The system includes inlets, catch basins, storm sewers, main drains, storage reservoirs, detention basins and pump stations.

Stormwater Detention Facility: A stormwater storage facility which temporarily stores surface runoff and releases it at a controlled rate through a positive outlet.

Stormwater Retention Facility: A stormwater storage facility which stores surface runoff. Stored water is infiltrated into the subsurface or released to the downstream drainage system or watercourse (via a gravity outlet or pump) after the storm event.

Streambank Erosion: Removal of soil particles from a bank surface due primarily to water action. Other factors such as weathering, ice and debris abrasion, chemical reactions, and land use changes may also directly or indirectly lead to streambank erosion.

Streambank Protection: Any technique used to prevent erosion or failure of a streambank.

Subdrain: An underground conduit, usually perforated and surrounded by an engineered granular filter material that is designed to permit infiltration for the purpose of collecting and conveying groundwater.

Subgrade Erosion: Erosion of the material underlying that portion of the stream bed which is subject to direct action of the flow.

Subsurface Disposal: Drainage of stormwater runoff into the subsurface by the process of infiltration. This is typically accomplished through the use of dry wells, engineered basin floors, etc.

Tailwater: The water surface elevation in the channel downstream of a hydraulic structure.

Thalweg: The line extending down a channel that follows the lowest elevation of the bed, see Invert. Not to be confused with the channels's centerline.

Total Freeboard: For an embankment dam, the vertical distance between the emergency spillway crest and the minimum crest elevation of the dam.

Total Sediment Discharge: The sum of suspended sediment discharge and bedload discharge or the sum of bed material discharge and washload discharge of a stream.

Transport Rate: Rate at which sediment particles are carried when hydraulic conditions exceed the critical condition for motion. Transport rates are calculated analytically by the use of transport functions.

Trash Rack: A metal bar or grate structure designed to prevent blockage of the structure by water-borne debris.

Trickle Channel: Also called the low flow channel, the trickle channel is that portion of a major channel which is sized to carry the normal low flow.

Underdrain: See Subdrain.

Uniform Flow: Flow of constant water area, depth, discharge, and average velocity through a reach of a channel.

Uplift Pressure: Pressure caused by uncontrolled seepage or groundwater flow beneath a structural slab which can lead to cracking and displacement of the structure.

Velocity Head: Represents the kinetic energy of the flowing fluid generally expressed as $V^2/2g$ in feet, but actually is the energy per pound of flowing fluid.

Vortex: Local current accelerations which cause a whirling or circular motion that tends to form a cavity or vacuum at its center, thus moving sediment toward the cavity.

Waters of the U.S.: All waters which are currently used, were used in the past, or may be susceptible to use in interstate or foreign commerce, including all waters which are subject to the ebb and flow of the tide.

Watershed: An area confined by drainage divides, often having only one outlet for discharge. See Basin Area.

Weep Hole: Openings in an impermeable wall or revetment to relieve the neutral stress or pore water pressure. Weep holes are typically combined with reverse filter drains to form a total system for seepage control.

Weir: A notch of regular form through which water flows. A weir may be a depression or notch in the side of an outlet structure or a depression of specific shape in the embankment of a stormwater storage facility. Classified in accordance with the shape of the notch, there are rectangular weirs, V-notch weirs, trapezoidal weirs and parabolic weirs.

Acceleration chutes, 7-5, 7-67

ADEQ, 8-15

ADWR, 2-3, 6-4, 6-26, 8-8, 8-22

- EM-1110-2-1601, 6-43
- 404 permit, 6-2
- HEC-1, 2-1, 8-40
- HEC-2, 5-29, 5-80, 6-27
- HEC-RAS, 5-29, 5-80, 6-27

USBR basin I, 7-49

USBR basins II, III, IV, 7-46

USBR basin V, 7-51

USBR basin VI, 7-59

Velocity:

- channel maximum, 6-11, 6-12, 6-15
- channel minimum, 6-10
- culvert maximum, 2-3, 5-3
- culvert minimum, 2-3, 5-3
- inverted siphon minimum, 5-79
- storm drain maximum, 4-2
- storm drain minimum, 4-2

Velocity head, 6-16

Vertical riprap basin drops:

- construction considerations, 7-45
- hydraulic design (general) 7-42
- maximum drop height, 7-42, 7-70

Vertical hard basin drop:
 construction considerations, 7-41
 hydraulic design (general) 7-38
 maximum drop height, 7-38, 7-70

Water harvesting, 8-35

Water quality, 8-36

Weed control, 8-32

Weighted-creep analysis, 7-24

Weir coefficient for catch basin, 3-23

Wire enclosed rock:
 channel lining, 6-7, 6-49
 design considerations, 6-50
 maximum channel velocity, 6-15
 maximum channel side slope, 6-15
 slope mattress lining, 6-50

WSPRO (FHWA), 5-80
